New oral anti-factor Xa agents are being developed. Rivaroxaban and apixaban are the two agents furthest along in development. Rivaroxaban has 66% renal excretion, whereas apixaban has only 25% renal excretion.^{44,53} Other antithrombotic agents being evaluated include oral heparins, other direct thrombin inhibitors, such as lepirudin, bivalirudin, and argatroban; defibrinating agents such as ancrod; anti-inflammatory agents, such as P-selectin inhibitors; factor VIIa inhibitors; tissue factor pathway inhibitor; and activated protein C.^{54,55} Lepirudin and argatroban have been approved for patients with HIT. The use of P-selectin inhibitors, an area of ongoing research, uses an anti-inflammatory approach to limit thrombus amplification without causing anticoagulation.

NONPHARMACOLOGIC TREATMENTS

Pain and swelling after an above the knee DVT can be decreased by approximately 50% by the use of strong compression stockings.⁵⁶ Additionally, walking with good compression does not increase the risk of PE, while significantly decreasing the incidence and severity of pain and swelling after DVT.^{57,58} Once patients are on therapeutic anticoagulants, they should ambulate while wearing compression stockings. The use of strong compression and early ambulation after DVT treatment can significantly reduce the pain and swelling resulting from the DVT and carries a 1 A level of evidence.^{26,56,57}

IVC Filters

The traditional indications for the use of IVC filters include a complication of anticoagulation, a contraindication to anticoagulation, and failure of anticoagulation. Protection from PE has been greater than 95% using cone-shaped wire-based permanent IVC filters.⁵⁹ The success achieved with filters has expanded the indications including free-floating thrombus longer than 5 cm, when bleeding risk with anticoagulation is excessive, when the risk of PE is felt to be very high, and to allow for the use of perioperative epidural anesthesia.^{60–62} Filters can be permanent or optional (retrievable). If a retrievable

filter is left in to become a permanent filter, the long-term fate of that filter has not yet been defined.

Filters are usually placed in an infrarenal location. However, they may also be placed in the suprarenal location or in the superior vena cava. Indications for suprarenal placement include high-lying clot, pregnancy, women of childbearing potential, or a previous device that has failed or become filled with clot. Sepsis is not a contraindication to the use of wire-based filters since the trapped material can be sterilized with antibiotics. Although filters have been placed under x-ray guidance, percutaneous techniques for filter insertion using bedside external ultrasound or intravascular ultrasound are now being recommended. Transabdominal external ultrasound is difficult in the setting of morbid obesity, overlying bowel gas, or open abdominal wounds. In these instances, intravascular ultrasound has been found to be more successful.⁶³ Other than one randomized prospective study on the use of filters as treatment of DVT (which is not how filters are traditionally used), evidence for the use of filters is given a 2 C level of evidence.^{26,64}

Thrombolytic and Surgical Procedures for Deep VTE

The incidence of chronic venous insufficiency after appropriate anticoagulant treatment for DVT has been reported to be as high as 23% after 2 years, 28% after 5 years, and 29% after 8 years.¹⁹ Thus the use of thrombolytic agents more rapidly to clear venous thrombosis has been suggested (Algorithm 102.1). By duplex ultrasound, spontaneous lysis time is 2.3- to 7.3-fold longer in segments with reflux than in segments without reflux.⁶⁵ Systemic thrombolysis in two small series revealed a decrease in the incidence of chronic venous insufficiency with streptokinase, as opposed to systemic UFH. However, results depend on complete thrombolysis. Because of this inability to predict complete lysis, combined with its bleeding potential, thrombolysis is recommended infrequently. However, urokinase administered directly into venous thrombi has led to an increase in enthusiasm and the publication of a national thrombolysis registry.^{66,67} In 473 patients, 287 of whom underwent follow-up, 312 urokinase infusions in 303 limbs were reported. Venous thrombi occurred in the iliofemoral segment in 71% of cases alone, without IVC involvement in 79%, and including the IVC in 21% of cases. Patients had acute disease in approximately two thirds of cases, 16% had chronic disease, and 19% had combined acute and chronic disease. Approximately 30% had prior DVT. Complete thrombolysis was achieved in 31% and partial lysis in 52% of cases. The mean amount of urokinase used was 7.8 million units, and the mean time of infusion was 53.4 hours. Successful lysis was predicated by acute DVT and no history of prior DVT. Complications included major bleeding necessitating blood products in 11% and minor bleeding in 16%. The mortality rate was 0.4%, the intracranial hemorrhage rate was 0.2%, and the subdural hemorrhage rate was 0.2%. Total lysis was noted in only 31% of the entire series; however, in patients with acute iliofemoral DVT, no previous symptoms, and the use of the popliteal vein access site, total lysis was more frequent. At 12 months, patency was 79% if lysis was complete, 58% with greater than 50% lysis, and 32% with less than 50% lysis. Absence of valvular reflux was found in 72% of cases with complete lysis, whereas overall valvular reflux was seen in 58% of cases.

It is important that aggressive therapies have been found to improve quality of life. A small randomized study demonstrated that thrombolysis is superior to anticoagulation in patients with iliofemoral DVT.⁶⁸ The use of lytic agents for DVT is now given a 2 B level of evidence.²⁶

Thrombolytic therapy for PE remains controversial. Although agents lysed thrombus effectively, recurrence rates and

patient mortality were not improved. However, the original studies were not powered to address this outcome. Results are best if patients are young, the embolus is less than 48 hours old, and the embolus is large. Streptokinase, urokinase, and tissue plasminogen activator have all been used.⁶⁹ All agents rapidly dissolve clot, but by 7 days, the advantages for all three agents decrease. The benefit of thrombolytic agents for PE thus appears to be greatest in patients who would die as a result of massive PE in the first hour after the PE occurs, which can occur in up to 10% of cases. However, more recent data suggest that thrombolysis may be useful in patients with right ventricular dysfunction without hemodynamic instability, and it has been suggested that thrombolysis will improve outcomes if patients have evidence of right heart changes.⁷⁰⁻⁷⁵ Additionally, thrombolysis therapy has been recommended in patients without pulmonary hypertension who are judged to have a low risk of bleeding.²⁶

Venous Thrombectomy. Iliofemoral venous thrombectomy has been advocated to prevent impending venous gangrene. This technique results in mechanical clearing of the venous circulation and may be combined with a temporary arteriovenous fistula. Thrombectomy uses a Fogarty balloon catheter passed from the femoral vein during Valsalva maneuvers. An arteriovenous fistula is constructed so that it can be taken down by nonsurgical techniques. Complete venography in the operating room is recommended, as back-bleeding is unreliable for the assessment of complete thrombus clearance. Thrombosis recurrence rates less than 20% have been reported. The incidence of PE during the first week after thrombectomy is equivalent to the incidence with anticoagulation only. The frequency of clinical success has been reported to be between 42% and 93%.⁷⁶ The largest series of 77 legs with a follow-up period of between 5 and 13 years revealed maintenance of patency but a steady decline in valvular competence over time.⁷⁷

In the only comparative study of iliofemoral venous thrombosis treatment comparing thrombectomy with anticoagulation (31 patients) versus anticoagulation alone (32 patients), iliofemoral vein patency was improved (76% vs. 35%), femoropopliteal patency was improved (52% vs. 26%), and the clinical outcome was better at 6 months (40% asymptomatic vs. 7%).⁷⁷ At 10 years, the number of patients available for follow-up had decreased to 13 in the thrombectomy group and 17 in the anticoagulation-alone group. Patency remained improved in the thrombectomy group (83% vs. 41%), and absence of popliteal reflux was found in 78% of the thrombectomy-plus-anticoagulation group compared to 43% of the anticoagulation-alone group.

Pulmonary Embolectomy. Surgical approaches for PE are indicated for patients with massive PE with hypotension who require large doses of vasopressors. These are often patients in whom thrombolytic agents have been unsuccessful. Open pulmonary embolectomy is associated with high rates of morbidity and mortality. Today, open pulmonary embolectomy is limited to those who require manual cardiac massage for hypotension or those in whom catheter pulmonary embolectomy fails. However, there may be a more expanded role for pulmonary embolectomy in the future.⁷⁸

Superficial Thrombophlebitis

Superficial vein thrombophlebitis (SVT) is a well-recognized clinical entity characterized by a painful erythematous and palpable cordlike structure, usually compromising the lower extremities but capable of affecting any superficial vein in the body. Thrombophlebitis is believed to have a multifactorial etiology, in which the Virchow triad of altered blood flow, changes in the vessel wall, and abnormal coagulation are recognized to play a significant role. SVT has been considered a

benign disease requiring only conservative management with compression, nonsteroidal anti-inflammatory medications, and lower extremity elevation. Recently SVT, especially above the knee superficial thrombophlebitis, has been reported to coexist with DVT, to propagate to popliteal or femoral level, and even to cause PE.⁷⁹⁻⁸³ A medical approach using anticoagulant therapy appears as the treatment of choice when there is above knee SVT with deep venous system involvement.

The incidence of SVT occurs in approximately 125,000 people in the United States per year.⁸⁴ However, the actual incidence is likely far greater as these statistics may be outdated and many cases go unreported. Approximately 54% to 65% of the reported cases affect females with an average age of 58 years old.^{79,85} The most frequent predisposing risk factor for SVT is varicose veins, occurring in 62% of patients. Other risk factors include the following: immobilization, trauma, postoperative states, age older than 60 years, obesity, tobacco use, history of DVT or SVT, pregnancy, puerperium, autoimmune disease, use of oral contraceptives or hormonal replacement therapy, and hypercoagulable state.^{79,85,86} Hypercoagulable screening should be considered in patients with ascending or worsening thrombophlebitis despite initial treatment.^{87,88} Malignancy has been reported as a risk factor for developing SVT, affecting 13% to 18% of patients.^{82,89}

The overall recurrence of SVT was described as 18% over 15 months, equally frequent in varicose and nonvaricose phlebitis. Deep venous reflux increases the recurrence rate to 33%, whereas hypercoagulable states increase the recurrence rate to 42% over the same period of time.⁹⁰

The clinical symptoms and signs for SVT are overt. Duplex ultrasound imaging of the affected extremity should be performed to rule out extension of the process into the deep venous system or concomitant DVT.^{87,91} Duplex ultrasound shows the extent of the SVT, its relation to the veins connecting with the deep vein system, and the presence of concomitant DVT. Additionally, duplex ultrasound allows checking the competence of the valves in the superficial and deep veins.⁹¹

Complete thrombophilia workup is not routinely recommended. However, it may be indicated in selected patients with recurrent primary thrombophlebitis or aggressive thrombophlebitis.⁹¹ Screening for underlying diseases, including malignancy or vasculitis, is performed if signs or symptoms suggest the presence of such problem.⁹¹

Treatment. Several therapeutic approaches have been proposed for patients with SVT. These include ligation or vein stripping of the affecting vein, elastic stockings, nonsteroidal anti-inflammatory drugs to reduce pain and inflammation, and variable doses of unfractionated heparin or LMWH followed by oral anticoagulant therapy. There is no consensus on the optimal treatment of SVT in clinical practice.

It seems clear that the course of treatment for SVT should be tailored accordingly to its location, concomitant DVT and if there is any associated infectious process. Thrombus locations in trunks of either the great or small saphenous vein may have the highest risk of extension into the deep vein system and thus require more aggressive treatment than other locations. The treatment for primary SVT localized in the distal great saphenous vein and tributary veins consists of ambulation, warm soaks, compression, and nonsteroidal anti-inflammatory (NSAID) agents.^{92,93} If the patient presents risk factors for DVT, pharmacologic prophylaxis should be considered seriously.⁹¹

Titon et al.⁹⁴ were among the first to compare different approaches in the medical treatment of SVT. In a multicenter study, 117 patients were randomized into three groups: fixed dose LMWH calcium nadroparin ($n = 38$), adjusted-dose LMWH calcium nadroparin ($n = 39$), and the NSAID naproxen ($n = 40$) for 6 days. At day 7, heat and redness were significantly less ($p < 0.001$) in both groups treated with LMWH compared to those given the NSAID. Additionally at 8 weeks, persistence of symptoms and signs was less frequent in

the LMWH treated groups ($p = 0.007$). Efficacy did not differ between the fixed and weight-adjusted dose of LMWH.

The management of SVT was further addressed in a randomized double-blind study describing 427 patients with documented acute symptomatic SVT of the legs.⁹⁵ Patients were randomly assigned to receive 40 mg enoxaparin sodium subcutaneously; 1.5 mg/kg enoxaparin sodium subcutaneously; oral tenoxicam 20 mg; or placebo, all once daily for 8 to 12 days. LMWH was associated with a lower incidence of SVT extension and/or recurrence, compared with placebo (OR 0.32; 95% confidence interval [CI], 0.16–0.65, and OR 0.33; 95% CI, 0.16–0.68, respectively), without major bleeding or HIT. There was no statistical difference with respect to 12-day outcomes between the active treatment groups. However, there was a trend in favor of LMWH.

The Vesalio Investigator Group compared two regimens of LMWH with each other.⁹⁶ A total of 164 patients were enrolled and randomized into two groups: prophylaxis group ($n = 81$) and treatment group ($n = 83$). After completion of 3 months, the cumulative rate of SVT progression and venous thromboembolism complications did not differ between the prophylactic (8.6%; 95% CI, 3.5–17.0) and therapeutic (7.2%; 95% CI, 2.8–15.1) groups. No patient in either group developed major bleeding, although one patient in each group developed clinically asymptomatic HIT. Clinical symptoms improved to a similar extent in both groups, and similar rates of minor extension or recurrent thrombophlebitis were observed during the follow-up period.

Prophylactic-dose intravenous (IV) UFH was compared in two studies.⁹⁷ Relative to elastic stocking alone, prophylactic IV UFH plus elastic stockings was associated with an 86% reduction in SVT extension and/or recurrence (OR 0.14; 95% CI, 0.03–0.67). Marchiori et al.⁹⁸ compared high- versus low-dose IV UFH. A nonsignificant 86% reduction in VTE (OR 0.14; 95% CI 0.02–1.23) and a 37% (OR 0.63; 95% CI, 0.21–1.88) lower rate of SVT extension and/or recurrence were observed in those patients treated with high-dose UFH. There were no episodes of major bleeding or HIT.

Low-molecular-weight heparin was compared with saphenofemoral disconnection for the treatment of proximal great saphenous vein thrombophlebitis in a prospective, randomized clinical study.⁹⁹ In this study, 84 consecutive patients diagnosed as presenting SVT alone, were divided into two groups treated with either saphenofemoral disconnection under local anesthesia with a short hospital stay ($n = 45$) or enoxaparin on an outpatient basis for 4 weeks ($n = 39$). In all, 30 patients per group completed the study requirements. In the surgical group, two patients (6.7%) presented complications of the surgical wound, one (3.3%) had SVT recurrence, and two (6.7%) had nonfatal pulmonary embolism. In the enoxaparin group, there was no progression of the thrombosis to the deep venous system or PE; there were two cases (6.7%) of minor bleeding and three (10%) recurrences of SVT. Even when the study found no statistically significant difference between the two groups in the treatment of SVT, the LMWH group demonstrated a significant socioeconomic advantage and confirmed the efficacy of LMWH treatment in resolving symptoms and signs and preventing DVT and PE.

Prophylactic-dose LMWH has the advantage over other equally efficacious techniques in resolving symptoms and signs and preventing DVT and PE in cases without concomitant DVT. Patients treated with LMWH do not require hospitalization, present less adverse effects, do not require laboratory monitoring in most situations, have a low risk of bleeding, and treatment is less expensive if hospitalization is not required. It is generally felt that medical management with anticoagulants versus surgical treatment is somewhat superior for minimizing complications and preventing subsequent DVT and PE development. On the other hand, surgical treatment with ligation at the saphenofemoral junction combined with stripping (with or without perforator interruption) appears to minimize superfi-

cial venous thrombus extension, which ultimately provides improved pain relief.¹⁰⁰

Septic thrombophlebitis requires treatment with broad-spectrum intravenous antibiotics. If rapid resolution of the cellulitis occurs, no treatment beyond a short course of antibiotics and standard treatment for the superficial thrombophlebitis are required. However, if the patient becomes septic, excision of the infected vein is required. With positive blood cultures, an extended course of antibiotics specific for the identified organism is indicated additionally.

Most episodes of uncomplicated superficial thrombophlebitis respond to conservative management. However, the recurrence rate for superficial thrombophlebitis has been estimated as between 15% and 20%.^{101–103}

CHRONIC VENOUS DISEASE

Normal Venous Anatomy

The lower extremity venous system is composed of deep, perforating, and superficial veins (Fig. 102.1).¹⁰⁴ The common femoral, femoral, deep (profunda) femoral veins in addition to the popliteal and tibial/peroneal veins make up the deep system. There is a concerted effort to replace the once named “superficial” femoral vein with simply “femoral vein” to alleviate the confusion the term “superficial” implies when treating what is actually a deep vein. The deep veins lie beneath the investing fascia of the muscles of the leg and thigh (the deep compartment). The saphenous veins have similarly undergone a change in name to the great saphenous (GSV) and small saphenous vein (SSV) to standardize the abbreviations that are otherwise extremely confusing. It has also become clear that the GSV and SSV lie within the superficial compartment and also within a saphenous compartment. The saphenous nerve lies within the GSV compartment, which places the nerve at risk of injury during surgery, but if the associated sensory loss occurs, it appears to have little impact on the patient's quality of life.¹⁰⁵ The sural nerve lies in close proximity to the SSV within its compartment. The superficial veins outside the saphenous compartment are called accessory saphenous veins and lie parallel to the GSV or SSV. The term *communicating*

FIGURE 102.1. Duplex image demonstrating the superficial compartment, which contains the saphenous compartment with great saphenous vein (GSV) (straight arrow) lying within and the deep compartment with femoral vessels (curved arrow) lying within.

vein is now reserved for those veins that interconnect with other veins of the same system, and the term *perforating vein* is reserved for those that penetrate the muscular fascia to connect superficial to deep.¹⁰⁴ In the past, perforating veins with rather constant anatomic location have been named for their discoverer (e.g., Crockett, Boyd perforators), but more descriptive terms designating location are now preferred.¹⁰⁴

The variability of the lower extremity venous system is well known, but only certain anatomic variations are of importance for current surgical practice. The popliteal and femoral veins have variable anatomy and are often duplicated much like the tibial veins. The deep femoral vein often connects directly or through tributaries to the popliteal vein. Although duplication of the GSV has been estimated to be present in up to 50% of patients in some studies, it is becoming evident that duplications of the true GSV lying within the saphenous compartment may be less common.^{106,107} The saphenofemoral junction often has at least four branches in addition to the GSV, but the arrangement and precise location of the branches is quite variable. The most cephalic branch is generally the superficial epigastric vein and is of some importance in new techniques for managing GSV reflux. The SSV is rarely duplicated (4%).¹⁰⁸ Although the SSV appears to pierce the deep fascia in the upper third of the calf, in reality the membranous layer forming the roof of the SSV compartment is thickened, while the muscular fascia disappears, which positions the SSV between the gastrocnemius muscle bellies.¹⁰⁸ In only 62% of limbs does the SSV actually end in the popliteal fossa.¹⁰⁸ The anatomy of the perforating veins becomes extremely important when considering surgery aimed at preventing reflux in the lower leg. Certainly, removing the GSV may not prevent the impact of perforator reflux if one ignores the fact that the posterior tibial vein perforators connect the posterior accessory GSV with the posterior tibial veins, rather than forming a direct connection with the GSV proper. Similarly, not recognizing the presence of paratibial perforators can result in an unsuccessful operation aimed at preventing calf perforator reflux.¹⁰⁹

With the exception of foot veins, the valves promote blood flow from superficial to deep and from caudal to cephalad in direction. The valves are made of a fine connective tissue skeleton covered by endothelium and are generally bicuspid, delicate, and extremely strong. The tibial and peroneal veins contain about 7 to 19 valves each. The popliteal vein contains one or two valves, and the femoral vein generally has three. About 70% of common femoral veins have a valve located within 1 cm of the inguinal ligament. Twenty-five percent of external iliac and 10% of the internal iliac veins have a valve.¹¹⁰ The common iliac vein generally has no valves. Within like lengths of the superficial venous system when compared to the deep veins, fewer valves are found (approximately seven to nine in the GSV and SSV). Perforating veins and even larger venules have venous valves.¹¹⁰

Variable numbers of venous lakes (1 to 18 sinuses) are found in the soleus muscle. These sinuses are valveless, floppy channels linked to small-valved venous channels that prevent reflux to the superficial system. The sinuses empty into the posterior tibial vein in the proximal calf. Within the gastrocnemius muscle, there are interlacing valved venous networks that coalesce to form a pair of venous channels that empty into the popliteal vein. These intramuscular venous chambers store venous blood and are crucial to calf muscle pump function.

The veins of the abdomen and pelvis begin at the inguinal ligament as the external iliac vein, which is joined medially by the internal iliac to form the common iliac vein. The internal iliac veins drain the pelvis via connections, such as the obturator, gluteal, and internal pudendal veins and their interconnections. To the right of the fifth lumbar vertebrae and aorta, the common iliac veins join to form the IVC. Compression of the left iliac vein by the right common iliac artery can lead to a venous obstructive condition, the May-Thurner syndrome. The IVC typically ascends to the right of the aorta and verte-

bral column terminating in the right atrium. Its direct tributaries are the lumbar veins, the right gonadal vein, the renal veins, the right suprarenal vein, the right inferior phrenic vein, and the hepatic veins. Other named veins generally join one of these tributaries to empty into the IVC. Because of the embryonic evolutions that lead to the “normal” IVC and its branches, variations are common. Duplication of the IVC occurs in 0.2% to 0.3% of cases, transposition or a left-sided IVC can occur in 0.2% to 0.5% of cases, and a retroaortic left renal (1.2%–2.4%) and circumaortic left renal vein (1.5%–8.7%) have also been reported.¹¹¹ In the face of IVC occlusion, veins of the chest and abdominal wall, the azygos and hemiazygos systems, and vertebral plexuses may play a prominent role in venous decompression.

Normal Venous Physiology

Under conditions of low volume or external pressure, many veins lying within muscle are demonstrated by duplex scanning to collapse in an elliptical configuration consistent with a thin vein wall and the lack of in situ external support.¹¹² With muscular relaxation, veins within these compartments change from an elliptical to a circular configuration to accept venous blood being emptied from the superficial system and delivered to the lower extremity by arterial inflow. Compliance is very high; in fact, increasing the venous volume by over two and one half times results in only a 0- to 15-mm Hg increment rise in pressure.¹¹³ This allows a significant amount of blood (at least 500 mL in the standing position) to become sequestered in the lower limb without a significant buildup of intraluminal pressure. However, once a vein reaches its full circular shape, further increases in venous volume result in a proportional increase in intraluminal pressure. The capacitance of the venous system has been met, and sustained venous hypertension results in decompensation noted as edema. Normally, modest exercise of the muscles will expel the blood volume and reset the capacitance of the venous system.

In contrast to intramuscular veins, duplex scanning demonstrates that large axial veins (e.g., femoral, popliteal) collapse in a circular manner. Supported/tethered on all sides by connective tissue, these veins are subject to equal external pressures along the vein wall and expand or collapse in a direct response to changes in volume.¹¹⁴ Their compliance mimics that of an artery in that pressure changes are more reflective of volume changes. They are conduit rather than compliance vessels.

The calf muscle and possibly the thigh muscles act as a pump, the “peripheral heart,” which can generate pressures of up to 300 mm Hg during exercise.¹¹⁰ Muscle contraction propels the blood toward the heart and lungs via the cephalad conduit veins. The valves in the proximal superficial and deep veins open to allow blood to move forward. The perforating vein valves close to prevent venous blood reflux from deep to superficial veins, thereby preventing high pressures generated in the deep system from affecting superficial structures (i.e., skin, soft tissues). In addition, blood moves centrally during exercise by compression of the superficial veins between the deep fascia and skin, but the pressure generated is only 100 to 150 mm Hg.¹¹⁰ As the calf muscle relaxes, the flow/pressure gradient falls and proximal vein valve closure prevents reflux. Arterial blood then slowly fills the venous system; valves in the foot veins and perforating veins open to allow the deep veins to fill from the superficial system replenishing the calf muscle pump venous sinuses.

The vein valve functions in a four-phase cycle: opening, equilibrium, closing, and closed phase. During equilibrium, flow separation occurs at the valve edge, the flow splits into two streams with one of the streams directed into the valve sinus possibly aiding in a self-cleaning step (preventing stasis). When maximally open, the two cusps create about a 35% narrowing of the outflow lumen, which may aid in outflow.¹¹⁵ It is interesting that most of the cycle has the valve in the open

position. Valve closure normally occurs within 0.5 to 1.0 second in response to retrograde blood flow and the loss of a pressure/flow gradient.^{116,117} Closure time is somewhat dependent on the stimulus to closure, and a flow velocity of at least 30 cm per second is required.¹¹⁸

An intravenous catheter placed into a foot vein can measure changes in venous pressure over time and with movement. These measurements reflect normal venous hemodynamics in the distal superficial venous system.¹¹⁰ When lying flat, a person's normal lower extremity intravenous pressure is about 15 mm Hg, but with standing the pressure rises to reflect the hydrostatic pressure of a column of blood from the heart to the foot catheter most reflective of the patient's height (generally ± 90 mm Hg). A hemodynamic study of venous function involves pressure measurements obtained during controlled exercise. The venous filling time (VFT) is the time required to arrive at a steady-state pressure after standing. Ten steps (one per second) causes a drop in pressure, and the lowest pressure, called the ambulatory venous pressure (AVP), is generally less than 45 mm Hg. The venous refilling time (VRT) is the time required, following exercise, to reach the baseline erect pressure. It is normally greater than 20 seconds. This rather simplistic measurement reflects a complex interaction of the venous conduits, the property of the veins, and the action of the peripheral pump.¹¹⁹ If one measures the venous pressure in deeper veins and in more central locations, the measurements would be considerably different, but such measurements are not commonly obtained in clinical practice.

Prevalence and Impact

Chronic venous disease (CVD) is a common, costly malady in Western countries. If one considers the entire spectrum of the disease, it affects more than 30 million Americans (more than half women).^{120,121} Varicose veins are observed in 15% to 25% of the adult population.^{122,123} Chronic venous insufficiency (CVI) is defined as venous pathology that results in advanced clinical symptoms (edema to venous ulceration). Skin changes suggestive of venous disease are noted in 6 to 7 million U.S. citizens, and venous ulcers occur in up to 2% of those with CVI (approximately 500,000 patients).^{120,124} Population studies confirm these earlier clinical observations.¹²⁵ The most recent population-based study supported by duplex imaging and using a modified CEAP classification (see later) demonstrated that 5.8% of those studied presented with edema, whereas 6.2% had skin changes and/or prior or active venous ulcers.¹²³ Furthermore, the annual cost to treat venous ulcers is estimated at greater than \$1 billion.¹²⁶ It is interesting that similar findings are noted throughout Europe.^{127–131} Relevant risk factors for varicose veins are advanced age, a positive family history, female gender, multiparity, and obesity based on epidemiologic studies.^{120,123,127,128,130–132} Risk factors for CVI are advanced age, positive family history, and obesity.^{123,127,131}

Pathophysiology and Etiology

Three pathophysiologic states exist: obstruction, valvular insufficiency, and calf muscle pump malfunction. These conditions reflect a failure of one or more of the components of the normal venous system and are not mutually exclusive.

Venous obstruction causes an increased resistance to blood exiting the lower extremity. It was once thought that venous obstruction was rarely the major underlying hemodynamic problem in patients with CVD. However, there are currently data to suggest that venous occlusive disease in combination with venous insufficiency is found in 55% of patients with CVI, especially those with the most severe symptoms.¹³³ Certainly, evidence exists that past estimates of venous occlusive disease in the pathophysiology of CVI were underestimates of its impor-

tance and prevalence.^{133–135} The result is elevated intravenous pressure noted clinically as pain especially after exercise.¹³³ If the deep system is primarily involved, the increased pressure generated with each calf compression may impact the perforating veins resulting in valvular malfunction and leading to venous hypertension in the superficial system and its capillary network. Asymptomatic primary iliac venous compression is quite common with intraluminal ($27 \pm 5\%$) and varying degrees of external compression (66%–88%) observed in the general population.^{136–141} Left common iliac vein compression by the right common iliac artery, as well as external iliac vein compression from the internal iliac artery on either side, have been described.^{140,142} It has been suggested that the nonthrombotic iliac occlusive lesion is a “permissive lesion” not clinically significant until other components of the lower extremity venous circulation fail, often presenting as valvular insufficiency.¹⁴³ The good results of iliac vein stenting in patients with CVI even in the presence of untreated reflux might be explained by eliminating this permissive lesion. In one of the largest experiences treating iliofemoral venous occlusive disease involving nearly 1,000 patients, compression of the common iliac vein was seen in 36%, external iliac vein in 18%, and both sites in 46% of limbs.¹⁴³ Of these patients, 53% of limbs had nonthrombotic compressive lesions (absent history of DVT, no venographic or ultrasound findings indicating previous DVT); 40% had postthrombotic obstruction; and 7% had a combined etiology. Furthermore, 20% of the patients were men, and 25% of the symptomatic lower limbs were on the right side. Intraluminal webs from repetitive trauma have been reported in 14% to 30% of symptomatic cases of the May-Thurner syndrome.¹⁴² Extrinsic compression of the iliac and pelvic veins may also be caused by tumor, fibrosis, or infection. Contents of a femoral hernia can crush the femoral vein, as can soft tissue tumors of the thigh. Arterial aneurysms can impinge on the femoral vein. The popliteal vein can be obstructed by a popliteal aneurysm or Baker cyst.¹⁴⁴ Aplasia of the vein or tumors of the vein wall have been described.^{144,145} Deep venous thrombosis is associated with inflammation and thrombus resolution resulting in external vein wall scarring with stiffening and thickening, as well as intraluminal recannulation with webs and bands. The venous valves are generally incorporated in the scarring process, leading to even more occlusive debris within the lumen. It is a common cause of venous occlusive disease due to its overall prevalence and association with chronic venous disease and clearly can involve any part of the venous system.

Valvular insufficiency may occur in any part of the lower extremity venous systems. It accounts for 85% of symptomatic CVD cases with a 70% incidence of primarily superficial and 30% primarily deep venous insufficiency (DVI) as determined by clinical experiences.^{134,135} Duplex imaging studies suggest that patients with minimal disease (varicose veins or less) have superficial reflux while those with edema, skin changes, and past or present ulcers have increasing presence of perforator and deep disease. In those with more advanced venous disease, reflux alone is observed in 80%, reflux and obstruction in 17%, and only 29% had obstructive disease alone.^{146,147} The presence of obstructive and reflux disease had the worse prognosis for the development of skin changes.¹⁴⁸ No matter the clinical stage, the superficial system is most commonly affected (90%) with GSV involvement in 70% to 80%, SSV in 15% to 20%, and nonsaphenous veins in approximately 10%. The deep veins are involved in about 30% and perforator veins in about 20%.^{146,147} Those with the most severe sequelae of venous disease have superficial reflux in 74% to 93% with 17% to 54% having only superficial disease.^{149–153} Fifty percent of patients have superficial with or without perforator disease, and less than 10% have isolated deep venous reflux.^{152–155} In those patients with venous ulcers, two vein systems were involved in 50% to 70% of patients, and all three systems were involved in 16% to 50% of patients. Since these duplex imaging studies mainly involve imaging of the lower extremity veins, the influence of proximal

venous occlusive disease may well be underestimated. Reflux allows the transmission of high venous pressures to the lower leg, while standing, that cannot be relieved by exercise. Primary valvular insufficiency may rarely be a consequence of congenital absence of valves.¹⁵⁶ More commonly, venous valve prolapse (elongated, floppy valves) or defects in the vein wall that cause the valve ring to dilate can result in malfunctioning valve cusps with retained valve architecture.^{157,158} The muscle cell dilating effect of estrogens may explain the genesis of varicose veins noted in the first trimester. Prolonged exposure to high venous pressures can cause vein dilation as occurs from an arteriovenous fistula or occupations requiring prolonged periods of standing. Roughly 50% of deep vein valvular dysfunction occurs secondary to DVT, whereas the remainder appears to be of a primary etiology with a 10% to 20% variance depending on the clinical experience being reported.^{134,159–161} Inflammation and thrombosis associated with DVT tends to cause valve scarring, whether or not recanalization is complete, leaving damaged valve architecture in contradistinction to primary valvular insufficiency. This classic differentiation between primary and secondary (or postthrombotic) pathology does not clearly exist when subjected to direct observation of the veins and valves at surgery. In fact, the two conditions can be present in the same patient as noted some 20 years ago.¹⁶² In these cases, the vein wall is thickened/fibrotic at the valve station or there is thickening of the valve cusps and/or intima. Pathologic study of eleven such veins demonstrated clear postthrombotic changes in six, but phlebosclerosis of a nonthrombotic origin in the remaining five.¹⁶³ Clearly, preservation of a rather normal valve architecture can be explained if primary reflux and sustained high pressure on the wall is the cause of the changes noted. Another theory is that rapid resolution of acute thrombi, an event known to occur, may have allowed these valves to escape damage or the valve itself may not have been directly involved in the thrombotic process.¹⁶⁴ The fibrotic process involves only the vein wall, and the valve cusps become floppy by virtue of a decrease in wall diameter resulting from a thickened, noncompliant vein wall.¹⁶³ The valve remains architecturally intact and can be repaired surgically, a situation once thought impossible in the postthrombotic patient.

There can be failure of calf muscle pump function. The pump becomes unable to generate the force needed to eject blood from the leg while standing, resulting in sustained venous hypertension. Patients with muscle disuse (e.g., paraplegia, traumatic injury, elderly or bedridden patients) may not have sufficient muscle for effective exercise. Pathologic conditions that result in muscle fibrosis (e.g., muscular dystrophy, multiple sclerosis) can destroy the calf muscle pump. Thrombus and scarring in the gastrocnemius and soleal veins can prevent blood from entering the pump resulting in a deficient ejection volume with contraction. Calf pump function and ankle range of motion are progressively diminished with increasing severity of CVI.^{165–168} Physical conditioning to improve calf pump function as a therapeutic maneuver has been studied in a small, randomized controlled trial and demonstrated improvement in both pump function and muscle strength.¹⁶⁹ With the exception of muscle rehabilitation, very little can be offered patients with some of these disorders.

Regardless of the etiology, the sequelae of venous hypertension/stasis are changes observed in the lower leg skin and subcutaneous tissues. Originally, ischemia from various causes was considered the etiology of the damage noted in the skin and soft tissue of the lower leg, especially ulceration.¹⁷⁰ More recent observations suggest that far from being simply an ischemic event, the end-organ response to venous hypertension is highly dynamic. The final answer is likely to involve a complex interaction of multiple factors that favor either continued destruction or the ultimate healing of the ulcer. Leukocytes, extracellular matrix, fibroblasts, and a host of other factors are recruited to heal the early endothelial injury and the more delayed soft tissue injury.¹⁷⁰ The soft tissue injury may result in

a chronic ulcer that requires growth factors to force the process to healing.¹⁷¹ Research remains active in this component of venous pathophysiology.

Clinical Signs and Symptoms

Venous disease presents in many ways. A telangiectasia, spider vein, is a confluence of dilated intradermal venules less than 1 mm in caliber. A reticular vein is a dilated bluish subdermal vein, usually 1 mm to less than 3 mm in diameter and usually tortuous. These venous abnormalities may or may not be accompanied by a larger, more deeply located, pathologic vein.

Hereditary varicose veins usually appear during the second decade of life. If a secondary etiology is involved (e.g., thrombosis, trauma), varicosities often present several years after the inciting event. These veins appear alone or in clusters as dilated, often bluish, serpentine, and palpable protrusions of branches of the GSV, SSV, or collateral veins lying beneath the skin within the subcutaneous tissues. Symptoms may be those associated with any type of CVD.

CVD can result in pain, edema, hyperpigmentation, stasis dermatitis or eczema, and/or venous ulcers. These changes often occur in the “gaiter” area just above the medial malleolus. Important perforating veins lie in this area. The observed hyperpigmentation is thought to result from extruded red blood cells that are degraded by macrophages leaving hemosiderin deposits.

Venous claudication is a pain syndrome experienced when walking and is associated with cyanosis, a sensation of increased swelling, and increased prominence of the superficial veins, which is relieved with rest in combination with elevation of the extremity.^{133,172,173} It may be so severe in rare cases that amputation is requested.¹⁷⁴ The most severe form is observed when venous incompetence is associated with obstruction and when the obstructive process is in a more proximal locale.¹⁷⁵

Critical to patient management and treatment evaluation is an accurate classification of the disease at any given time. Each patient should be stratified according to the clinical picture, the etiology, the anatomic distribution, and the pathophysiology (CEAP) classification system.¹⁷⁶ This classification system helps the physician to define the venous disease so that a focused and appropriate management strategy can be formulated. An extension of the clinical classification system is available to quantify the extent of venous disease and, therefore, to evaluate the patient's clinical response to treatment.^{177,178} The anatomic and pathophysiologic improvement following a treatment of venous disease can be scored using the Venous Segmental Disease Score,¹⁷⁸ whereas the Venous Disability Score provides some information of what a person can do while afflicted with venous disease.¹⁷⁸ Quality of life (QOL) surveys have been developed specifically for patients with venous disease to help determine the impact of the disease on the patient's life and the effect therapy has on the patient's overall well-being.^{179–182} Consistent application of these surveys to the postsurgical outcome of patients has yet to be achieved, but is imperative to improve our ability to precisely determine the effect and benefit of a given intervention.

Diagnostic Evaluation

The diagnosis of CVD begins with a thorough history and physical examination. The history is important to provide hints to familial coagulation disorders or events in the patient's history that may impact the care of the chronic disorder. Use of the CEAP clinical classification (Table 102.3) will provide a snapshot of the patient being examined, whereas use of the more detailed venous clinical severity score (Table 102.4) will allow some impression of how any therapy is performing on the patient's behalf.

TABLE 102.3 CLASSIFICATION**CLINICAL CLASSIFICATION OF CHRONIC VENOUS DISEASE**

■ CLASS	■ DESCRIPTION
0	No visible or palpable signs of venous disease
1	Telangiectases and/or reticular veins
2	Varicose veins
3	Edema
4a	Skin changes (pigmentation and/or eczema)
4b	Skin changes (lipodermatosclerosis and/or atrophie blanche)
5	Healed venous ulcer
6	Active venous ulcer
S (in addition to the class)	Symptoms including ache, pain, tightness, skin irritation, heaviness, muscle cramps as well as other complaints attributable to venous dysfunction
A (in addition to the class)	Asymptomatic

Venous duplex ultrasonography provides a B-mode image of the vein as well as spectral analysis of the blood flow within it. It is essential to clarify the etiology (*E* of CEAP; congenital, primary, or secondary), better define the anatomic location (*A* of CEAP; specific veins can be imaged with spectral analysis to determine reflux), and aid in determining the pathophysiology (*P* of CEAP; reflux, obstruction, or both) of the venous problem. Once considered unnecessary in the evaluation of patients with simple varicose veins, it has become common practice prior to intervention for superficial reflux due to anatomic variability, variability in veins affected, and the need for precise targeting of veins during endoluminal intervention.^{106,183–185} Venous duplex imaging clearly visualizes deep and perforator veins and valves as well.

Valvular insufficiency is defined as prolonged reflux time through a valve following a provocative test. A reflux time of more than 0.5 second is considered abnormal with a rapidly deflating distal cuff during the provocative test, whereas longer than 1.0 second is considered the cutoff following manual compression.^{116,117} A recent study suggests that these values may be appropriate for the deep calf veins, but that 1.0 second should be the cutoff for larger femoropopliteal veins even when using the rapidly deflating distal cuff method.¹⁸⁶ The latter has yet to be confirmed by other investigators. The examination is performed in the upright position in these

TABLE 102.4**DIAGNOSIS****VENOUS CLINICAL SEVERITY SCORE**

■ ATTRIBUTE	■ ABSENT 0	■ MILD 1	■ MODERATE 2	■ SEVERE 3
Pain	None	Occasional, not restricting activity or requiring analgesics	Daily, moderate activity limitation, occasional analgesics	Daily, severely limiting activities, regular use of analgesics
Varicose veins ^a	None	Few, scattered: branch VVs with competent GS/SS	Multiple: single-segment GS/SS reflux	Extensive: multisegment GS/SS reflux
Venous edema ^b	None	Evening ankle edema only	Afternoon edema, above ankle	Morning edema above ankle and requiring activity change, elevation
Skin pigmentation ^c	None or focal, low intensity (tan)	Diffuse, but limited in area and old (brown)	Diffuse over gaiter distribution (lower 1/3) or recent pigmentation (purple)	Wider distribution (above lower 1/3) and recent pigmentation
Inflammation	None	Mild cellulitis, limited to marginal area around ulcer	Moderate cellulitis, involves most of gaiter area	Severe cellulitis (lower 1/3 and above) or venous eczema
Induration	None	Focal, circumalleolar (<5 cm)	Medial or lateral, less than lower third	Entire lower third of leg or more
No. of active ulcers	0	1	2–4	>4
Active ulceration, duration	None	≤3 mo	>3 mo and ≤1 y	Not healed >1 y
Active ulcer, size ^d	None	<2 cm diameter	2–4 cm diameter	>4 cm diameter
Compressive therapy ^e	Not used or not compliant	Intermittent use of stockings	Wears elastic stockings most days	Full compliance: stockings + elevation

GS, greater saphenous; SS, small saphenous; VV, varicose vein.

^aVaricose veins must be >4 mm diameter to qualify so that differentiation is ensured between C1 and C2 venous pathology. Occasional or mild edema and focal pigmentation over varicose veins does not qualify for C3 or C4.

^bPresumes venous origin by characteristics (e.g., brawny [not pitting or spongy] edema), with significant effect of standing/limb elevation and/or other clinical evidence of venous etiology (i.e., varicose veins, history of DVT). Edema must be regular finding (e.g., daily occurrence). Occasional or mild edema does not qualify.

^cFocal pigmentation over varicose veins does not qualify.

^dLargest dimension/diameter of largest ulcer.

^eSliding scale to adjust for background differences in use of compressive therapy.

reports. Many other provocative maneuvers to generate venous reflux exist (Valsalva, standardized Valsalva, etc.) in addition to performing the test in different positions (e.g., 15° Trendelenburg, sitting).¹⁸⁷ Each may be acceptable if standardized for an individual laboratory and supported by the literature. Venous obstruction is seen as thickened, scarred, and constricted veins with poor flow and diminished augmentation following distal and/or proximal compression. Respiratory variation is lost as a result of local disease or proximal occlusion. Similar imaging and spectral analysis can be performed to determine obstruction or insufficiency in the superficial and perforator veins. Reflux in the superficial system is considered abnormal with parameters similar to the deep calf veins and is determined by provocative compression.¹⁸⁷ Disease within the SSV should not be ignored because it can have a significant clinical impact as an isolated event.¹⁸⁸ Incompetent perforating veins are generally larger in diameter, thereby allowing a larger volume of blood flow during reflux, and are considered to demonstrate reflux with a reflux time longer than 0.5 second.¹⁸⁵ There is some thought that this cutoff should be decreased to 0.35 second, but currently the 0.5-second cutoff remains used in most laboratories.¹⁸⁶ By imaging the entire lower leg venous system, the surgeon is provided a detailed roadmap of all veins with confirmation of obstruction or reflux if present within segments commonly separated by valves. Of course, isolated venous valvular insufficiency or obstruction may have little clinical impact on the patient, and therefore clinicians have attempted to quantify the pathology by adding up segmental disease, determining mean duration of reflux, determining peak reverse flow velocity, and so forth.^{117,174} Although average scores correlate with disease severity, individual results have little predictive value, and therefore, these methods have not been widely adapted. The issue of common standards for the performance and interpretation of venous duplex studies still plagues efforts to define venous disease, but many find it the most versatile and reproducible imaging device currently available.^{187,189} This is often the only diagnostic evaluation needed for the evaluation of superficial and even perforator disease requiring treatment as a first stage in patient management.

A difficult area of investigation from a noninvasive perspective is the pelvic, abdominal, and chest veins. CT and MRI can provide details of anatomy and the effect of surrounding structures in areas not visualized by duplex evaluation.^{190–192} However, as with all vascular laboratory studies, clinical correlation is mandatory because anatomic presence does not necessarily translate into a clinical problem. For example, iliac vein compression is commonly seen in an asymptomatic population.^{136–141} These studies can be particularly useful in evaluating for pelvic congestion syndrome.¹⁹³

Plethysmography assesses the overall hemodynamics of the lower extremity venous system. Air plethysmography (APG) can measure several venous hemodynamic parameters and is the study currently most used. A plastic cylinder filled with air is fitted over the calf and foot. Changes in leg volume with positional change or exercise are detected by pressure changes in the cylinder. The venous filling index is 90% of resting standing venous volume (VV) divided by the time it takes to reach 90% of VV as the patient shifts from the supine to standing position (mL/s). A venous filling index of 2 mL/s or less is indicative of a competent venous system, and higher values suggest venous insufficiency.^{194,195} The use of tourniquets to separate superficial from deep or perforator disease has not been reliable, but it can be useful in specific cases.¹⁹⁶ After an erect baseline reading, patients exercise by dorsiflexion or heel raises to empty the calf veins. The ejection fraction is the amount of blood propelled cephalad with a single muscle contraction divided by VV. After a series of 10 ankle flexions, the volume remaining in the leg is referred to as the residual volume and when divided by the VV is called the

residual volume fraction. An ejection fraction of greater than 60% and residual volume fraction of less than 35% suggests that the calf pump is working well.^{167,197} The residual volume fraction is relatively equivalent to the AVP.^{126,196} Significant outflow obstruction is determined by occluding venous outflow until a stable plateau is reached. The thigh cuff causing the venous occlusion is rapidly deflated, and the difference between maximal volume and that volume present 1 second later divided by the total calf volume is called the outflow fraction (OF). Normally, 38% or more of venous blood is expelled from the leg in 1 second.¹⁹⁵ Several other plethysmographic methods (e.g., impedance, photo) and even light reflex rheography have evaluated similar venous parameters. The ability of these techniques to reliably eliminate the presence of significant venous occlusion in patients with CVD is questioned.^{178,198} Although these plethysmographic methods can differentiate patients with severe CVI (class 3 or greater) from those without disease, stratification by symptom severity is not possible, and therefore, its use in the treatment of patients with minor symptoms, such as varicose veins or telangiectases, is also questionable.¹⁸⁷ Because these studies do not provide an anatomic image of the venous system or evaluation of individual venous valve function, many physicians combine one of these studies as an estimate of global hemodynamics, in patients with advanced disease (clinical grade 3 or higher), with ultrasonography to complete the venous evaluation.

As in acute venous disease, venography has no significant role in the initial evaluation of patients with CVD. Ascending venography can suggest venous occlusion when duplex imaging clearly demonstrates an open system.¹⁸⁹ Even the presence of significant collaterals on transfemoral venography may underestimate the degree of venous occlusion documented by intravascular ultrasound.^{133,199} The use of ascending venography is selectively used in specific cases to complement noninvasive studies when considering intervention in the deep venous system.

The technique of descending venography has been well described.²⁰⁰ Descending venography is used to determine valve leaflet integrity and anatomic location, and to demonstrate the extent of reflux.²⁰⁰ Assessment of the competence of the profunda femoris venous system in addition to the femoral system is imperative. If it is a competent system, it may be a source for a valve transposition or may predict success with an isolated proximal femoral vein repair.^{201–203} Certainly, descending venography is not infallible in determining the presence or absence of a normal valve.¹⁶³ Raju et al. report that descending venography misrepresented the presence of a valve in 11% of cases (a valve considered present was not at operation) and missed an intact valve in 25% of cases (a valve thought absent was actually present).¹⁶³ However, when combined with a careful venous duplex examination, it is currently the best method available to determine preoperatively if an in situ reconstruction will be possible.

Intravenous pressure measurements can aid in the diagnosis of venous disease, but is invasive and generally used only when invasive surgery of the deep system is being considered. This study can help to determine the overall magnitude of reflux.¹²⁶ AVP has been shown to correlate with the presence of venous ulceration, with each 10-torr increase above 30 torr corresponding to a 10% to 15% increase in the incidence of venous ulceration.²⁰⁴ Direct lower limb intravenous pressure measurements obtained prior to and after thigh cuff compression and compared to arm intravenous pressure have been suggested as a method to determine the presence or absence of venous obstruction and to determine if obstruction is compensated or not.^{163,205} The inventors of this intravenous measurement now question the reliability of this or any other hemodynamic studies to accurately rule out significant iliac obstruction and recommend intravenous ultrasonography to clarify the issue.¹⁹⁸ Although intravenous pressure measurements and

venography were once the gold standard for evaluating venous disease, duplex scanning with the addition of plethysmographic or intravascular ultrasonographic techniques, in specific cases, are the anatomic and functional tests of choice in current medical practice.¹⁹⁴

Treatment Options and Results

Medical Therapy. Compression has been the mainstay of the medical treatment for all stages of CVI for centuries. The goals are to manage clinical symptoms and to control venous hypertension. Roughly speaking there are two types of compression: elastic (e.g., support stockings or long stretch bandages) and inelastic (e.g., Unna paste boot, short stretch bandages, multilayer (four-layer) bandage or Velcro band devices). The degree to which any particular bandaging is one or the other will depend on the care provider who applies the compression along with other factors. The mechanical effect is dependent on the level and type of compression as well as the underlying venous pathology. Initial narrowing of deep and superficial calf veins on standing as determined by duplex imaging is observed at 20 mm Hg.²⁰⁶ There is a trend to decreasing residual venous volume and venous filling index, which translates into decreased edema and improved quality of life (QOL) data in those with early mild disease.^{207–210} Consistent narrowing of superficial and calf veins occurs at a median of 30 to 40 mm Hg pressure on standing, whereas complete occlusion occurs at a median pressure of 70 mm Hg. Complete occlusion is not the goal. At 30 mm Hg and standing, inelastic bandages significantly decrease the venous filling index and venous volume in patients with venous ulcers and deep venous reflux.²⁰⁷ It took 40 mm Hg to decrease the venous filling index when using elastic stockings. The higher the pressure exerted up to 60 mm Hg, the more impressive the changes in residual venous volume and decrease in venous filling index.²⁰⁷ Therapeutic calf compression improves calf muscle pump function expressed as a reduction in residual volume fraction during walking as well.²¹¹ High compression was helpful in reducing great saphenous and femoral vein diameter (by duplex imaging) at a constant pressure of ≥ 40 mm Hg and reduced venous reflux (by APG) at 60 mm Hg.²¹² Overall, these effects on the underlying veins help to improve the venous pump and decrease the venous volume in the lower extremity. It is interesting that elastic stockings maintain a rather constant pressure during exercise and at rest. Alternatively, inelastic wraps demonstrate a more dramatic increase in pressure during exercise since they do not stretch but have decreasing pressure with recumbence as the edema exits the leg and the bandage maintains its shape.²¹³ This may explain why inelastic wraps are much better tolerated when left on day and night. It also explains why such compression should be changed more frequently early in treatment and less frequently later as the degree of edema requiring control lessens.

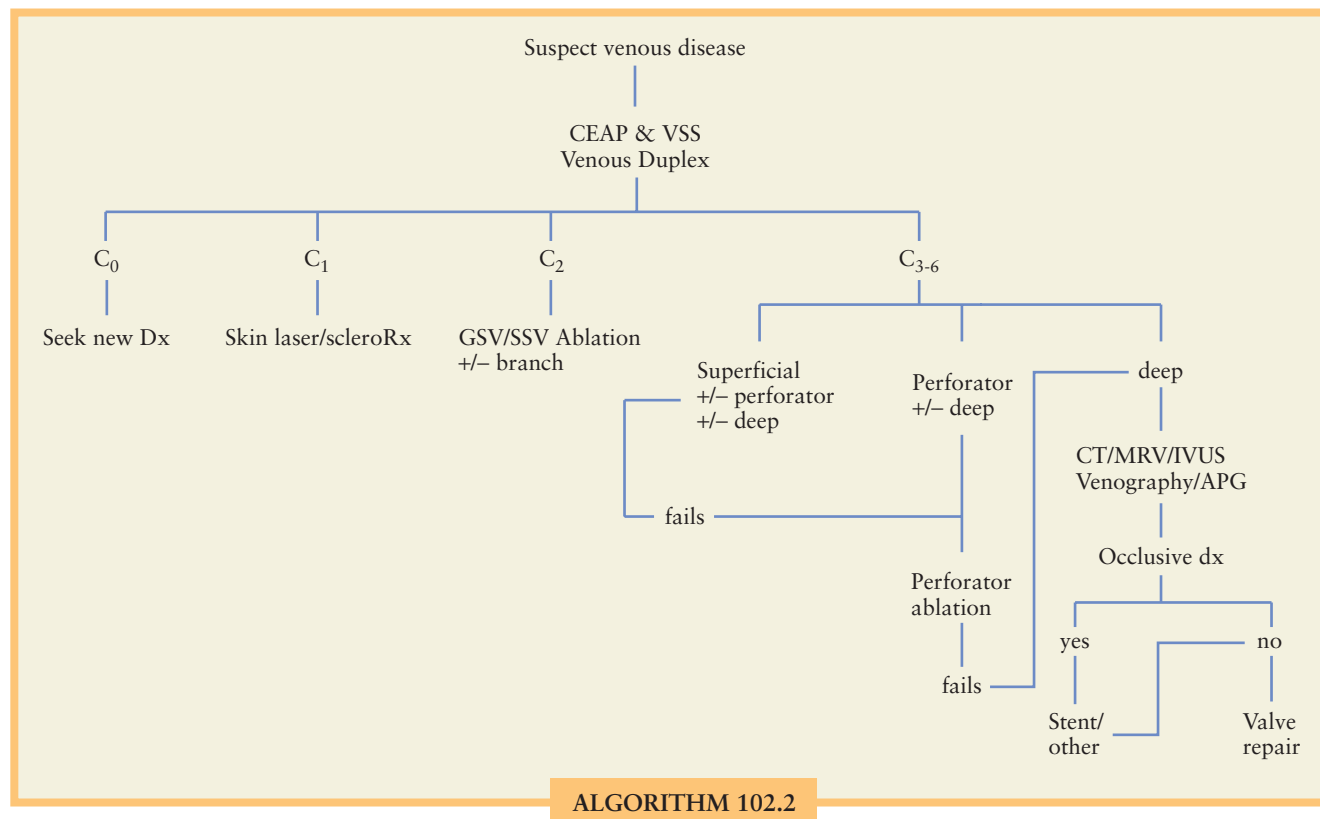

There are data to suggest that extended use of elastic compression may impede the microcirculation and thereby jeopardize tissue viability.²¹⁴ However, it is also apparent that compression has a positive influence on the local skin and soft tissues in the face of edema. A compression stocking at 30 mm Hg of compression will significantly improve the capillary filtration rate in patients with C_{4–6} disease, and stiffer stockings do better.²¹⁵ By decreasing the subcutaneous pressure in the perimalleolar area, medium and strong compression can promote extracellular fluid reabsorption and improve sodium subcutaneous tissue clearance.^{216,217} There are data to indicate that skin transcutaneous oxygen tension is diminished and the skin capillary density depressed as a result of venous insufficiency, but this can be improved with compression (edema reduction).^{218,219} Compression can increase microcirculatory flow velocity and may ameliorate the inflammatory injury and fibrosis associated with chronic venous insufficiency.

^{213,218,220,221} Cytokines, such as vascular endothelial growth factor and tumor necrosis factor, decrease with compression therapy and correlate with ulcer healing.²²² Furthermore and in contradistinction to the first statement in this paragraph, standard compression can actually increase arterial blood flow in some circumstances.^{213,223} The lymphatic system is involved in this derangement, which can also be improved with compression.²¹⁹ In those with significant arterial occlusive disease (especially with ABI < 0.50 and even 0.80 in some cases), compression is contraindicated since an external pressure could decrease the distal perfusion to critical levels.^{213,224–226} This may especially be true for elastic compression garments since constant pressure is applied. However, inelastic bandages applied with a resting pressure of less than 20 mm Hg and used with active exercise reduce edema and increase arterial flow similar to the use of intermittent pneumatic compression.²²⁷

Evidence-based medicine confirms our clinical impression and has been applied to the use of compression garments for the treatment of CVI. Two areas have substantial evidence to demonstrate that compression is statistically beneficial. First, elastic compression stockings (30–40 mm Hg) significantly reduce the incidence of the postthrombotic syndrome after an episode of DVT.^{228,229} Second, compression increases ulcer healing rates when compared to no compression. Multilayered systems are more effective than single-layered systems, and high compression (25–35 mm Hg at ankle) is more effective than low compression, but there is no clear difference in the effectiveness of different types of high-compression dressings (three layer, four layer, short stretch, Unna boot) (recommendation grade A).^{228,229} High-compression (30–40 mm Hg) stockings can be used to heal ulcers with an expected 90+ % rate of healing within 6 months.^{230,231} The compliant patient can expect healing rates in the 90% range, whereas those non-compliant may have healing in only 50% of cases.^{230,231} The evidence for the use of compression for other clinical stages of CVI is less clear and best studied by an initiative of the International Union of Phlebology with grade B recommendations defined as those based on only one large or several smaller randomized controlled trials (RCTs) and grade C recommendations based on observational studies or consensus meetings. Certainly, compression aids in preventing the recurrence of venous ulcers, but the optimal pressure and type of compression is not clearly defined (recommendation grade B).^{213,229,232} In one study, recurrence of the ulcer was nearly ensured if the patient was noncompliant in the use of maintenance compression, whereas only 29% of those compliant experienced a recurrence.²³⁰ The prophylactic use of compression in patients with a prior venous ulcer appears cost-effective.²³³ There is Grade B evidence for the use of compression stockings in C_{05,15,3} afflicted patients (10–21 mm Hg in the first two and 23–32 mm Hg in the latter) to relieve symptoms.^{213,229} Patients with varicose veins both asymptomatic (23–32 mm Hg) and symptomatic (34–46 mm Hg) may be helped with compression stockings (recommendation grade C).^{213,229}

In the final analysis, inelastic wraps or multilayer wraps are preferred for the *therapy phase* of venous disease (ulcer healing), but compression stockings of sufficient strength are also effective. When the ulcers are healed and the extremity is relatively free from edema, elastic wraps such as compression stockings are used to maintain a stable clinical condition (*maintenance phase*). In addition, elevating the legs when possible during the day, avoiding prolonged periods of standing or sitting, and elevating the foot of the bed 4 to 6 inches above the heart while sleeping are adjunct components of conservative therapy.^{234,235}

Intermittent pneumatic compression (IPC) provides pulsatile emptying of the venous system and can have a positive impact on the inflammatory injury and fibrosis associated with CVI.^{213,220} A Cochrane review with last update in 2008 found conflicting results when IPC was used alone or as an adjuvant to compression therapy to heal venous ulcers.²³⁶ Certainly, one

ALGORITHM 102.2

ALGORITHM 102.2. Treatment of chronic venous insufficiency.

RCT of 45 patients has demonstrated its use in patients with long-standing ulcers (at least 3 months' duration) comparing standard ambulatory compression with or without the addition of IPC. At 3 months, 10 of 21 ulcers healed with the addition of IPC, whereas only 1 of 24 healed with standard care.²³⁷ It does appear to aid in healing very recalcitrant ulcers with sufficient raw data to allow Centers for Medicare & Medicaid Services (CMS) to permit payment after all other compression therapies have been unsuccessful.

Structured exercise can improve dynamic muscle strength and calf muscle pump function in patients with essentially all levels of CVI from varicose veins to venous ulceration.^{169,238,239} It is unclear whether such exercise improves ulcer healing rates per se.

In Europe, various oral agents (e.g., diosmin, rutoside) have been touted to improve the feeling of heaviness, fatigue, and even edema of CVD, but these agents are not available in the United States. Drugs potentially useful in treating patients with venous ulcers are available in the United States. Pentoxifylline provides a small incremental benefit in ulcer healing and works best as an adjunct to compressive therapy.²⁴⁰ The trade-off appears to be a greater percentage of gastrointestinal adverse effects. Prophylactic use of systemic antibiotics in the treatment of venous ulcers is not recommended and may select only resistant organisms. One randomized clinical trial in 47 patients compared elastic support bandages only versus those also treated with systemic antibiotics. There was no statistical difference in healing rates of ulcers or in changes of the microbiologic flora.²⁴¹ Certainly, an established infection (cellulitis or deeper) must be treated as it would be at any site.

Topical pharmaceuticals have been evaluated as a means of improving venous ulcer wound healing. Topical antibiotics have found little use in this capacity and may retard wound healing and cause allergic reactions.²⁴² Growth factors and cytokines, in addition to compression, when provided as isolated topically

applied agents, have not demonstrated efficacy when compared to placebo. Reviews of the literature demonstrate inconsistent results or studies with insufficient data to determine with any certainty the efficacy of such adjuvants.^{243,244} Several topical dressings applied on the ulcer bed and beneath the compression dressing have been investigated to determine if ulcer healing could be improved. Hydrocolloids (e.g., DuoDERM), foams (e.g., Allevyn), alginates (e.g., Sorbsan), hydrogels (e.g., Intra-Site gel or Debrisan) and others (e.g., OpSite) have been studied. Insufficient data are available to make firm conclusions, but it is clear that the nature and amount of the exudates present may provide a rationale for the benefit of one or the other of these dressings in a given patient.²⁴⁵⁻²⁴⁷ The failure of medical measures or patient dissatisfaction with the results being obtained initiates a more invasive approach.

Surgical Therapy. The use of surgical intervention in the realm of venous disease as in all areas of vascular surgery is driven by the documented presence of disease, the risk of the intervention planned, and the expected outcome (Algorithm 102.2).

Telangiectasia, Reticular Veins, Branch Varicose Veins. Percutaneous laser energy can be used to treat telangiectasias up to 0.7 mm in diameter with reasonable success. For matting and telangiectasias less than 0.5 mm diameter, the flashlamp pumped dye laser (595-nm wavelength) is well studied.²⁴⁸ The potassium titanylphosphate (KTP) laser of wavelength 532 nm is applicable to those 0.7 mm or less.²⁴⁹ Since melanin is the prime competing light absorber to hemoglobin in the body, the increased epidermal melanin in the tanned skin risks long-lasting hyperpigmentation, and therefore, percutaneous laser therapy should not be preformed in those with a suntan.

Sclerotherapy (needle injection of caustic solutions directly into superficial veins) has long been advocated for treating varicosities remaining after saphenous ablation, small isolated

varicosities, telangiectasias, and reticular veins.^{250–252} Sclerotherapy alone appears an effective treatment for branch varicosities in patients without major saphenous reflux and appears effective when combined with GSV ablation to control branch varicosities.^{253–255} The most common sclerosing agents are sodium tetradecyl sulfate, sodium morrhuate and hypertonic saline (23.4%) with some use of combination of 25% dextrose with 10% saline. Polidocanol used extensively in Europe is not yet commercially available in the United States. Most agents are not specifically approved by the FDA for sclerosing veins but have been used for decades in many cases and in some were available before FDA approval was required (e.g., sodium morrhuate).²⁵⁶ All act to damage the vein endothelium, inducing inflammation and scarring with ultimate lumen collapse.^{250,256} Foam sclerotherapy is the addition of air to liquid sclerosing agents, particularly detergent sclerosants, to allow a more protracted contact of sclerosing agent to the vein wall. The technique is the current technique of choice for many phlebologists, especially for larger veins.^{253,257} Modification of the sclerosing agents, by producing a foam, adds a component to the agent that converts its use to off-label. The exact concentration of sclerosant, liquid or foam, used for sclerotherapy is dependent on vein size and agent used.^{250,256} These interventions are generally outpatient procedures.

Common complaints including burning, stinging, itching, and muscle spasm are observed with sclerotherapy injections.^{258,259} Extravasation of the agent can cause fat or skin necrosis, ulcerations, and/or hyperpigmentation of the surrounding skin.²⁵⁸ Posttreatment veins are often brown as opposed to the blue-red pretreatment color. Microthrombectomy appears to reduce postsclerotherapy pigmentation, especially in veins 1 mm or less in diameter.²⁶⁰ Other potential complications of sclerotherapy include allergic reactions and toxicity if too much agent is used at one sitting.^{250,258} Therefore, a limited amount of sclerosing agent is typically injected during a single setting. Rarely, ocular events or even cerebrovascular events have been observed following foam sclerotherapy and, therefore, must be discussed with the patient prior to its use.^{259,261}

Phlebectomy (ambulatory phlebectomy, stab avulsion, stab phlebectomy, microphlebectomy, and microextraction are synonymous terms) is a technique in which varicose veins are removed through small stab incisions with hooks or small mosquito clamps used to pull the vein from its bed. Several phlebectomy instruments are available.²⁶² It can be performed in an ambulatory setting with local anesthesia or in conjunction with a more invasive procedure and more extensive anesthesia. One small randomized controlled study suggests that this approach may have improved results over sclerotherapy.²⁶³ Which approach is best remains a point of contention in the literature. In some cases, the need for reintervention may be tolerable based on the minimally invasive nature of the procedures. Complications are generally minor and of low risk (<2%) including development of telangiectasia, blistering, hyperpigmentation, and missed varix.²⁶⁴ Tumescant anesthesia has allowed for extensive interventions with little pain on an ambulatory basis.²⁶⁵ Such field anesthesia allows for another method of phlebectomy, powered phlebectomy, involving a modified arthroscopic shaver with transillumination, which allows venous clusters to be illuminated, morcellized, and aspirated. When compared to ambulatory phlebectomy, there is no benefit in patient cosmetic scores or satisfaction, and the recurrence rate at one year is 15% higher.²⁶⁶ The added cost and lack of patient preference will likely prevent this technique from becoming widely adopted.

Saphenous Vein Stripping/Ablation. Duplex imaging of patients prior to invasive saphenous treatment has proven that not all saphenous veins per se are incompetent when varicosities exist. In such cases, saphenous preservation leads to good results.²⁶⁷ If saphenous insufficiency is present, some method of

controlling reflux is required for best results. Removing the refluxing vein from the venous system is the current best solution. The vein can be stripped from its bed and discarded. The procedure is called saphenous vein high ligation and stripping. Lower leg deep venous occlusive disease is not an absolute contraindication to removal of the saphenous system and may actually be indicated in patients with mixed obstruction/reflux disease and is often the first step in cases of combined deep and superficial insufficiency.^{268,269} Preoperatively, with the patient standing to fully dilate the veins, the varicosities are marked with a permanent marker for later operative visualization. The operation includes ligation and disconnection of the GSV at the saphenofemoral junction followed by complete removal of the vein to the knee. If the below knee greater saphenous vein is incompetent based on preoperative diagnostic studies, it may also be excised. The method of vein removal may involve the introduction of long metal or plastic stripping wires with removable heads of varying size (i.e., Codman), the perforate invagination (PIN) stripper, or various other devices aimed at pulling the vein from the leg.^{270,271} Both GSV and SSV can be treated by these methods, taking into account required patient positioning and anatomic variability especially of concern in the case of the SSV.²⁷⁰ Among properly selected patients undergoing GSV high ligation and stripping, recurrent saphenous varicosities will be noted in less than 25% of cases at 2 years, but increases to 41% at 5 years and 62% at 11 years depending on the rigor of patient evaluation.^{271–273} These results serve to highlight the chronicity of varicose vein disease and places in perspective the expectations for other forms of saphenous ablation.

Another method of removing the GSV from the venous circulation is to thermally heat the inside with radiofrequency-generated heat.^{274,275} Placed percutaneously or rarely by venous cutdown, the probe is sequentially heated throughout the length of the GSV. Tumescant anesthesia is administered within the saphenous compartment providing anesthesia, a heat sink, and some venous compression during the procedure. The cumulative vein occlusion rate reported from a venous registry is 87.2% at 5 years.²⁷⁶ Nearly 6% of patients had SSV and accessory saphenous vein interventions in this registry. Direct comparison to standard GSV vein stripping demonstrated comparable results in terms of recurrent varicose veins (14.3% vs. 20.9%) with an improved quality of life score even 2 years after surgery.²⁷⁷ The newest rendition of this procedure involves using a 7-cm-long heating probe placed at the end of the catheter, which is heated to 120°C for 20-second intervals sequentially down the length of the vein. The time for ablation is significantly decreased, and early work would suggest that at 6 months all veins were effectively removed from the venous circulation (99.6%).²⁷⁸ Long-term results are not available for this latest technical modification.

Alternatively, laser energy of various wavelengths (810–1,320 nm) delivered via a 600-μm bare-tipped fiber will cause a localized thermal injury to the vein wall.^{279–281} Early success is excellent with 90% to 100% freedom from recurrent varicosities. Elimination of reflux at a rate of 80% has been documented in 3-year follow-up.²⁸² Some have found utility of this newer method for the SSV.²⁸⁰ High-volume tumescant anesthesia provides a heat sink and, therefore, protection from collateral heat damage. When delivering endoluminal therapy aimed at obliterating the vein lumen, energy is delivered beginning about 1 to 2 cm below the superficial epigastric vein to preserve lower abdominal wall venous drainage and to prevent thrombosis of the deep system, and this is true for any technique using thermal energy for these procedures.

Hamel-Desnos et al.²⁵⁷ found GSV ultrasonography-directed foam sclerotherapy to be 84% effective in eliminating reflux for 1 year. Midterm results with ultrasonography-directed foam sclerotherapy in 175 patients reports a 2-year primary success rate of 55% with a 77% secondary success rate in preventing recurrent reflux.²⁸³ The long-term results of the VEDICO trial would suggest that substantially more veins

are present at 10 years when foam is used as a single modality than when surgery or surgery and foam are used.²⁵³ If recurrence without reintervention is the goal, sclerotherapy appears to be at a disadvantage. A meta-analysis suggests that over time sclerotherapy loses any advantage over older methods of vein ablation, which is also confirmed by individual case series.^{250,254,257,284,285} Newer techniques of sclerotherapy lack long-term evaluation.

Complications of GSV surgery are rare but include wound infection, DVT, nerve damage, and hematoma formation to mention the more prominent.^{272,286,287} Saphenous nerve injury can result in an area of numbness around the knee or foot but is often clinically irrelevant.^{105,122} Complications from SSV stripping are also typically rare but include bleeding, hematoma formation, sural nerve damage, DVT, and wound infection.²⁸⁸ These same complications are reported for radiofrequency and laser ablations, possibly at a slightly lower incidence for some such as nerve paresthesia. DVT risk is about 1% for all procedures.^{272,275,281,282,286,287} A complication unique to radiofrequency and laser procedures is thermal damage to adjacent structures, such as nerve or skin that appear to be mitigated by tumescent anesthesia.²⁷⁴ Complications as well as short-term and midterm freedom from recurrence for both radiofrequency and laser saphenous vein ablation compare favorably with standard stripping, and both may provide some early patient benefit.^{275,281,282}

Perforator Vein Ablation. Ligation of perforating veins can be an effective treatment for patients with isolated perforator vein incompetence. This procedure can be performed in conjunction with saphenous vein removal. Perforating vein ligation can be performed via an open or minimally invasive endoscopic technique. A Linton-type procedure uses an incision along the medial or posterior lower leg and creation of subfascial flaps.²⁸⁹ The perforating veins are directly ligated. If a skin ulcer is present, this can be débrided. If a large amount of soft tissue and/or fascia is involved, a skin graft can be placed to aid healing once the diseased tissues are removed.²⁸⁹ Alternatively, an endoscopic technique (subfascial endoscopic perforator surgery [SEPS]) can be used.²⁹⁰ Subfascial dissection is performed using sharp and blunt balloon dissection to allow direct video-enhanced ligation and division of perforating veins with or without CO₂ subfascial insufflation to increase visualization and decrease the risk of air embolization. The SEPS procedure has demonstrated decreased symptoms and a near 90% ulcer healing rate at 2 years.²⁹¹ Wound complications are less common after SEPS (0–10%) compared to the open method (12%–53%) with comparable outcomes.²⁹²

Both of the aforementioned procedures are more invasive than several percutaneous methods of perforator ablation, which can be accomplished under local anesthesia and with minimal skin disruption. No matter the ablating energy delivered (radiofrequency, laser, or chemical), ultrasonographic access, operative monitoring and confirmation of results is routine. Prevention of energy delivery to the deep system prevents unwanted thrombosis. Various sclerosing agents have been used with minimal risk of DVT or skin infection, and with an immediate success of 90% to 98% and a 2-year maintenance of occlusion of nearly 80%.^{293–295} Radiofrequency ablation demonstrates a greater than 90% early ablation rate with more than 90% free of reflux at 1 year.^{296,297} Laser energy of various wavelengths have been used for this procedure with reports of about 100% occlusions immediately and 85% to 90% occlusion rate at 6 months.^{297,298} Whether perforator ligation is required in addition to saphenous surgery for advanced CVD when both systems demonstrate insufficiency remains debatable.²⁹²

Iliac Stenting and Venous Bypass. Endovascular stenting of iliac vein stenosis/obstruction has improved the symptoms of venous occlusive disease including decreased edema and pain symptoms, and improved quality of life parameters.^{111,133,173,299–301} It

FIGURE 102.2. Open valvuloplasty to repair an insufficient valve can be accomplished by various venotomy incisions. **A:** The method of Kistner. **B:** The method of Raju. **C:** The method of Sottiriuri. **D:** The method of Tripathi and his colleagues.

will often result in healing of venous ulcers, many of which have associated untreated lower leg venous insufficiency, at an initial rate of 68% with only 8 of 101 healed ulcers recurring within 5 years whether performed for primary or postthrombotic occlusion.³⁰¹ Parameters of venous reflux are not worsened following resolution of the occlusive iliac vein occlusive disease.³⁰¹ The primary and assisted primary stent patency rates at 3 years are 75% and 92%, respectively, and at 6 years 69% and 89%, respectively (Fig. 102.2).^{301,302} Intervention was performed in the presence of significant clinical symptoms (C₃ or C₂ with pain) and greater than 50% morphologic stenosis found on transfemoral venography or intravascular ultrasonography.^{133,301,302} Potential complications include DVT, access site complications, retroperitoneal hematoma, and other catheter- and balloon-related problems with essentially no mortality associated with the procedure.^{198,301–303} When technically feasible, endovascular intervention has replaced more invasive approaches.

The open surgical procedures use native saphenous vein or polytetrafluoroethylene (PTFE) graft material as the conduit to bypass from a nondiseased distal vein to a disease-free proximal vein. Vena cava reconstructions often use PTFE grafts to allow a proper size match.³⁰⁴ Preoperative venous pressure studies are often obtained to document venous hypertension.³⁰⁵ Iliac vein decompression has been used in the instance of extrinsic compression by an overlying right iliac artery (e.g., May-Thurner syndrome). If the iliac vein is severely stenosed or occluded, cross-femoral venous bypass or direct repair of the iliac vein can be performed.^{191,306} Patient survival should be considered prior to aggressive intervention if iliac vein compression is due to a cancerous encroachment. The cross-femoral venous bypass (Palma procedure) is performed by passing a vein graft or graft material via a suprapubic subcutaneous tunnel to the contralateral femoral vein. The saphenous vein or prosthetic graft is then

connected to the unaffected femoral vein by an end-to-side technique. The key to success of this surgery may be graft diameter. If the native vein is less than 4.5 mm in diameter, better success may be achieved with a 10-mm diameter PTFE graft, although others would question whether PTFE is superior to vein in this location.^{304,305} An arteriovenous fistula is generally used to increase flow through the graft in the immediate postoperative period. This fistula can then be ligated in 1 to 3 months or left open long-term if no unwanted sequelae are noted. In one series, venous reconstruction for iliofemoral and IVC obstruction reported a 62% 3-year patency with the Palma procedure demonstrating the overall patency of 83% at 4 years.³⁰⁴ Mortality was minimal and wound complications rare. In current practice, these procedures are generally used only when a percutaneous approach has failed.

Indications for a saphenopopliteal bypass are symptomatic patients with isolated femoral or popliteal vein occlusion, a patent common femoral and ilio caval system, a nonvaricose saphenous vein, and femoral phlebitis inactive for at least 1 year. In addition, conservative therapy must have failed and venous hypertension must be documented. These distal to proximal venous bypasses use autogenous vein as the conduit of choice, and bypasses extend from distal to proximal nondiseased segments.³⁰⁵ This operation is rarely performed.

Although not yet proven as a method of treating occlusive venous disease due to prior thrombosis, some data suggest that endophlebectomy (operative removal of synechiae and septa) of iliac, femoral, popliteal, and even tibial veins is possible and can result in a 77% primary patency rate at 8 months.³⁰⁷

Venous Valve Repair or Replacement. During the conduct of these operations, several observations influence what the surgeon does for a given patient. If operative handling of the suspect valve results in vasoconstriction and secondary competence (often determined by a standard strip test), an external valvuloplasty or a prosthetic sleeve technique may be viable options.³⁰⁸ For a valve station requiring in situ repair, careful adventitial dissection of the valve attachment lines facilitates proper venotomy when required and helps to verify the feasibility of valve repair.¹⁶⁰ A lack of valve attachment lines may signify the destruction of the valve as a postthrombotic sequela, prompting other than an in situ repair.¹⁶⁰ Valvuloplasty of any sort is most commonly performed in the femoral or popliteal location due to size and hemodynamic considerations.

An internal valvuloplasty or an open direct valve repair has been the mainstay for the repair of primary venous valvular

reflux for decades. This technique involves venotomy and suturing of the elongated valve leaflets under direct visualization with fine polypropylene suture (7 or 6-0) to tighten the valve cusps. Kistner³⁰⁹ reported success with a longitudinal venotomy extending through the valve commissure in 1968 (Fig. 102.3). Raju championed a supracommissural approach involving a transverse venotomy at least 2.5 cm above the valve.³¹⁰ Sotturrai devised a hybrid approach (a T-shaped venotomy), using a supralvalvular transverse venotomy with distal extension into the valve sinus.³¹¹ A “trapdoor” approach involving two transverse incisions (supralvalvular and infravalvular) connected by a single vertical incision through the commissure has been described (Fig. 102.3).³¹² Plication of approximately 20% of the valve leaflet length tends to restore valve competency in most cases.³¹³

The technique of external valvuloplasty offers the advantage of valve repair without venotomy.³¹⁴ It is performed by placing sutures transmurally through the valve attachment lines, and when tied, reduces the commissural angle and vein diameter resulting in a competent valve. The valve leaflets are generally not captured or reefed by this method. Reported results suggest that it may be less durable than the more precise open valvuloplasty, but patient selection plays a key role.³¹⁴ A modification (limited anterior plication) involves only anterior vein dissection and then reefing of the cusps using a running mattress suture from a point 3 to 4 mm proximal to the angle of the valve cusp insertion lines up to the angle of valve cusp insertion.³¹⁵ About 3 mm of the vein wall is incorporated into the stitch to approximate the cusps. This technique was developed with the aim of decreasing vein dissection and resultant external scarring. It has been described in conjunction with saphenous vein stripping and limited to the femoral vein valve. Results after 10-year follow-up demonstrated improved VRT and decreased AVP in patients with moderate deep venous valvular incompetence.³¹⁵ Thus, it shows promise as a mode of therapy for highly selected patients. Another modification of this technique features the use of an angioscope.³¹⁶ A side branch of the GSV allows introduction of an angioscope, which is advanced into the femoral vein to a position above the incompetent valve, and external sutures are then placed under direct vision.³¹⁶ Following a learning curve while using the angioscope, Raju et al. demonstrated good clinical and competency data with the transcommissural technique without the use of the angioscope with 30 months of follow-up.³¹⁷ In these last two methods, the venous valve cusps are actually engaged with the suture, and

FIGURE 102.3. Cumulative primary, assisted-primary, and secondary patency rates of 603 limbs after iliofemoral stenting. The lower numbers represent limbs at risk for each time interval (all standard error of the mean <10%). (Adapted from Neglén P, Hollis KC, Olivier J, et al. Stenting of the venous outflow in chronic venous disease: long-term stent-related outcome, clinical and hemodynamic results. *J Vasc Surg* 2007;46: 979–990.)

therefore, the cusps are tightened directly much as in the open method of repair.

External banding has been used when dissection vasospasm renders a valve spontaneously competent. The technique uses an external sleeve made of synthetic material wrapped circumferentially around the vein at the site of the valve and tightened to diminish the size of the vein lumen until the valve is competent. The sleeve is then anchored in place to the adventitia by sutures to avoid slippage. It has achieved good results when used in select patients.^{201,318,319} One group of investigators have been more aggressive with this approach, using the technique in patients with more severe valvular reflux and often placing multiple external cuffs.³¹⁸

Venous valve transplantation is an option when the valve is absent or destroyed. This procedure was first reported clinically by Taheri et al. in 1982.³²⁰ A 2- to 3-cm segment of upper extremity vein containing a competent valve (or a reparable one) is first removed. The incompetent femoral vein is opened below the takeoff of the profunda femoris vein, and the axillary vein segment is sutured into place following the removal of an appropriate length of femoral vein. The popliteal location may be more appropriate if the femoral location does not control all axial reflux into the leg, for example, if the profunda femoral vein system is also incompetent. The proximal anastomosis may be accomplished first to confirm the competence of the newly transplanted valve and to allow distention and lengthening of the vein/valve to facilitate the distal anastomosis. For vein transplantation in trabeculated postthrombotic veins, investigators have excised intraluminal synechiae to create one acceptable lumen for transplantation.³²¹ Interrupted sutures are preferred to avoid suture line stenosis.³¹³ Valve competence is determined by the intraoperative strip test. An external sleeve can then be placed to prevent late dilatation of the repaired segment, and because approximately 40% of axillary vein valves are incompetent at explant, a bench repair may be required to restore competency.^{160,313} Should a bench repair be necessary, the transcommissural external valvuloplasty technique appears to have better results than the standard external valvuloplasty,¹⁶⁰ and success has been achieved with internal open valvuloplasty.³²²

A less common option for the postthrombotic syndrome is valve transposition. If a venous valve is competent in one of the major thigh venous systems, then a transposition procedure can be performed placing the incompetent venous system below the competent valve. Most commonly, the femoral system is incompetent and the profunda femoris valve remains competent. Here, the incompetent femoral vein can be transected and reimplanted distal to the competent valve in the profunda femoris vein. Alternatively, the incompetent femoral system can be placed below a competent valve in the GSV, or when the profunda femoris venous system is incompetent, it may be placed distal to a competent valve in either the femoral vein or the GSV. A technique has been described for transposition of the ipsilateral valve-competent GSV to the femoral vein and subsequent ligation of the femoral vein proximally yet distal to the takeoff of the profunda femoris vein to escape problems with diameter mismatch.³²³ At 10 years, 55% of the patients were reported to be ulcer free.

Aggressive venous valve surgery requires appropriate consideration of perioperative adjunctive care: prophylactic antibiotics, intraoperative heparin use especially if the vein is opened, the use of pneumatic compression devices postoperatively, and the use of low-molecular-weight heparin or intravenous heparin in the postoperative period. Some use closed suction drainage of wounds to avoid hematoma and seroma formation. Warfarin should have an initial target INR range of 2.0 to 2.5 for the first 6 weeks and some would advocate a subsequent decrease to 1.7 to 2.0 until 4 months when it is discontinued. Adjustments are made to accommodate those with an increased risk of thrombosis. One suggested long-term regimen is minidose warfarin, which uses daily doses of 1 to 2.5 mg to

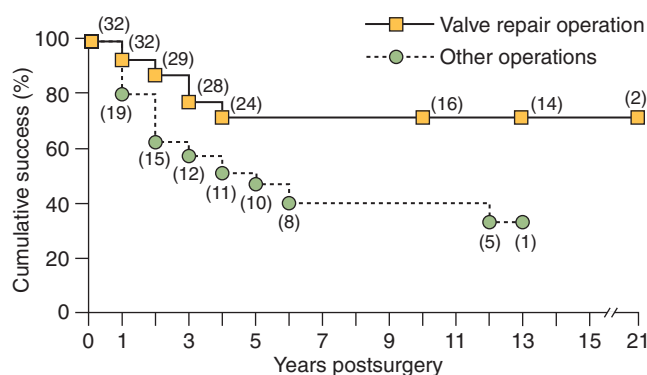

FIGURE 102.4. Life-table demonstrates cumulative clinical success rate based on type of valve reconstruction procedure. The valve repair operation is valvuloplasty as performed by Kistner and associates via the Kistner technique. “Other operations” refer to valve transpositions ($n = 14$), superficial femoral vein valve transplantations ($n = 2$), and combined valve repair and transposition procedures ($n = 3$). Numbers in parentheses indicate the number of valve repairs remaining in the study at that time point. Significant difference exists between valve repair versus other operations. (Adapted from Masuda EM, Kistner RL. Long-term results of venous valve reconstruction: a four to twenty-one year follow-up. *J Vasc Surg* 1994;19:391.)

prevent thrombosis.^{160,324} Although many surgeons encourage the use of compressive support, patients often do not comply but still have an acceptable clinical result.^{162,163}

Valve repair procedures are well tolerated by most patients and have a low morbidity, as well as essentially zero mortality in most series.¹³⁵ Hematoma and seroma formation are noted in less than 15% of cases depending on the level of anticoagulation used.^{162,313,325–327} DVT occurs in less than 10% of cases in most series and even if higher is not associated with clinical sequelae, while the PE risk is well less than 1%.^{160–162,313,325–327} Wound infections have been seen in 2% to 7% of cases.^{160,162,313,327}

The Kistner et al.³²⁸ long-term follow-up of internal valvuloplasty spans decades and is reported in life-table format (Fig. 102.4). Valve competency is 60% to 70% at 5 years in most series.^{161–163,201,310,312,327–333} In general, a patent and competent valve translates into clinical improvement and a healed ulcer, whereas the reverse is true with recurrent reflux. This is true for all types of single-station venous valvular reconstructions. External valvuloplasty without direct cusp repair (isolated wall diameter reduction) appears to perform less well in all aspects than open valvuloplasty.^{201,327} However, the transcommissural technique, which does directly repair the slack valve cusps, performs much like open valvuloplasty with a competency rate of greater than 60% at 3 years and a greater than 70% ulcer-free rate up to 5 years.³¹⁷ External banding performs adequately in select cases or as an adjunctive procedure during other venous surgery.^{201,318,319}

The valve transposition operation experience demonstrates clinical improvement in 50% to 60% of patients after 3 to 5 years of follow-up.^{135,161,162,323–326,328–332} The valve competency rate varies from 30% to 80% and is reflected in the clinical improvement noted.^{135,161,162,323–326,328–332}

Valve transplantation is undertaken in the most complex and difficult conditions. Clinical improvement is seen in about 50% of patients even at 8 years of follow-up, and it remains a good option in cases where other techniques are not possible.^{134,135,313} There does not appear to be a difference between reported competency rates or clinical results when considering the location of valve repair (femoral vs. popliteal), but overall the competency rates reported are inferior to internal valvuloplasty.^{310,320,332,334–339}

There are data to support the observation that repairing multiple valves in the same axial system translates into longer

clinical benefit, but this approach does, of course, add risks at the initial operative intervention.^{317,318,327,340}

In general, patients with postthrombotic reflux tend to have more problems maintaining healed ulcers than those with a primary etiology of reflux, as noted from the results of internal valvuloplasty (generally a primary etiology) versus those requiring transplantation or a transposition operative approach.¹⁶²

Valve Substitutes. For those patients with chronic DVI and no autogenous valve available, a valve substitute is the only alternative. Many experimental attempts using allografts and synthetics have been unsuccessful.³⁴¹ Three substitute valves—a cryopreserved venous valve containing allograft, a cadaveric cryopreserved pulmonary monocusp patch, and a small intestinal submucosa bicuspid stent mounted valve—have had isolated, but often unsustained success when reaching the clinical arena.^{342–344} The stent design and percutaneous route of the last-mentioned device is quite innovative; however, substrate fibrosis has lead the investigators to study the use of an autogenous valve with good preliminary animal results.³⁴⁵

Autogenous tissue appears to be the only material which currently can act as a substitute valve with some hope of success in the clinical arena. Using donor vein, after trimming adventitia and part of the media, to fashion semilunar cusps within the deficient recipient vein, Raju and Hardy¹⁶⁰ have reported acceptable clinical results. Another approach invaginates a stump of the long saphenous vein into the femoral vein to fashion a bicuspid valve; 19 of 20 reconstructions were patent and competent at a mean of 10 months with one valve demonstrating reflux.³⁴⁶ No other series have reproduced these findings to date. The newest innovation has been to use an ophthalmic knife or other fine tool to dissect the intima/media wall of the thickened postthrombotic vein wall into one or two sheets and thereby fashion the valve cusp(s).³⁴⁷ This technique has been reproduced by another investigator.³⁴⁸ A recent improvement has been to place two sutures on the cusp(s) to hold the valve in the semiopen position and thereby to prevent valve collapse and improve neovalve competence. The results with this modification include 21 operations (mean follow-up 11 months) with all valves competent, a 95% ulcer-healing rate, and two recurrences (9.5%).³⁴⁹

Surgical Wound Care

Débridement to healthy tissue when required benefits the rate of ulcer healing and does not lead to a higher risk of systemic infection.^{242,350,351} It is especially beneficial when evaluated as adjuvant care to the standard methods of venous ulcer wound care.^{246,352}

For resistant venous ulcers, skin grafting is an option. These ulcers can be extensive, and skin grafting allows for coverage of raw surfaces to speed the healing process. Once the ulcer has a clean base of granulation tissue, a split-thickness skin graft can be applied. There are reports on improved healing with skin grafting for chronic venous ulceration.³⁵³ Skin grafting is generally considered only when ulcer healing has not occurred following diligent conservative management. An alternative or precursor to an autologous skin graft may be one of several skin substitutes. Various skin substitutes have been used to aid in venous ulcer healing (e.g., fresh allografts, porcine dermis, etc.), but for most there are insufficient data available to determine whether venous ulcer healing is improved.³⁵⁴ However, the biologically active bilayered human skin equivalent with an allogenic epidermal and dermal layer has demonstrated more promise.^{246,354} Falanga et al.^{355,356} randomized 309 patients into one of two groups but only 275 were fully analyzed: Group 1 received human skin equivalent and compression, while group 2 received dressing (made to look the same as the intervention) and compression. At 6 months, 92 of 146 (63%) in

group 1 and 63 of 129 (48%) in group 2 healed ($p < 0.05$), and time to complete healing averaged 61 days in group 1 and 181 days in group 2.^{355,356} Porcine small intestine submucosa (SIS) is primarily a collagen-based extracellular matrix with retained biologically active components. Sixty-two patients received SIS plus a nonadherent dressing covered by a four-layer compression bandage, whereas 58 patients received the same treatment without SIS application. With SIS, 63% healed in 12 weeks, while only 40% did so in the same period without the addition of SIS ($p = 0.02$), and when adjusted for ulcer size SIS was three times as likely to heal as treatment for the control group ($p = 0.007$).³⁵² Of those that healed, none recurred in 6 months in the SIS group, whereas 30% of the control group experienced a recurrent ulcer. This manuscript was included in a recent review of the literature as a RCT demonstrating significance when used to heal venous ulcers.²⁴⁶

The Pelvic Congestion Syndrome

This distressing clinical condition can result from gonadal vein and/or hypogastric vein reflux. Pelvic pain is a constant complaint. Gonadal vein reflux may be best managed with gonadal vein excision due to its many areas of potential reflux, but an endovascular approach using coils, sclerosants, or a combination can also be successful and is gaining in popularity.³⁵⁷ Hypogastric vein reflux may be best managed by percutaneous embolization.³⁵⁸ When the elimination of proximal reflux does not resolve superficial varicosities, the management involves techniques used for saphenous vein branch varicosities.

CHAPTER 103 ■ SURGICAL PHYSIOLOGY OF INFANTS AND CHILDREN

FEDERICO G. SEIFARTH AND DAVID K. MAGNUSON

KEY POINTS

- 1 During the 8-week embryonic period, developmental events transform a fertilized egg into a “preorganism” that is composed of all the specialized tissues and organ systems required for future independent life; the subsequent 32-week fetal period involves accelerated growth and continuous organ maturation.
- 2 The fetus utilizes glucose as its primary energy substrate.
- 3 Maternal and placental mechanisms maintain an optimal temperature for fetal development; the net heat produced by fetal metabolic activity must be transferred away from the fetal environment to avoid a rise in temperature.
- 4 Neonates and children have significantly higher energy requirements than adults.
- 5 Breast milk is a complex mixture of macromolecules that changes as the growing infant’s needs change; the usable energy content of milk is divided almost equally between carbohydrates and lipids.
- 6 At 12 weeks’ gestation, water constitutes 95% of fetal mass; this declines to about 80% by 32 weeks’ gestation and to 75% at term.
- 7 The determinants of gas exchange are total alveolar ventilation, ventilation/perfusion matching, diffusion, and extra-pulmonary shunt; the mechanical properties of the lung affect gas exchange primarily by determining the amount and distribution of ventilation. Regulation of pulmonary blood flow determines ventilation/perfusion matching and the efficiency of gas exchange.
- 8 Respiratory distress syndrome, or hyaline membrane disease, is the most common cause of respiratory distress in neonates and one of the primary causes of neonatal mortality in developed countries.
- 9 The variations of extracorporeal membrane oxygenation share underlying principles: the partial diversion of blood from the patient to an external membrane oxygenator, ex vivo exchange of oxygen and carbon dioxide, and return of blood to the circulatory system.
- 10 At birth, circulatory patterns, hemodynamics, and gas exchange transition are characterized by the cessation of placental blood flow and gas exchange and the simultaneous increase in blood flow and gas exchange in the lungs.
- 11 Most mechanisms of physiologic control in the gastrointestinal tract are present at birth, although continued post-natal maturation results in ongoing adjustments over time.

This chapter introduces a variety of physiologic issues relevant to the care of infants and children with surgical disease. Reviewed are some of the basic physiologic concepts that govern clinical management, delineating some of the differences between pediatric and adult patients. These differences may be merely quantitative when comparing adults with adolescents and older children. The distinction between neonates and older patients, however, is frequently of a more dramatic and qualitative nature. These differences are the consequences of two unique conditions: the functional immaturity of organ systems during the transition from fetal to neonatal life and the demands placed on the physiologic machinery of the neonate by the overriding priority of growth. Whereas homeostasis is a valid concept on a small scale, in a larger sense the concept of a “steady state” is paradoxical in the newborn infant. Virtually every physiologic function in the infant is influenced in some way by the exponential growth that occurs during the first year of life. That growth, and the metabolic activity it demands, is perhaps the single most important property that differentiates the neonatal patient from the adult.

GROWTH AND METABOLISM

Growth, Development, and Prematurity

- 1 The 40-week gestational period is divided by convention into an 8-week embryonic period and a 32-week fetal period. During the embryonic period, developmental events occur that transform a

fertilized egg into a “preorganism” that is composed of all the specialized tissues and organ systems required for future independent life. The subsequent fetal period is characterized by accelerated growth and continuous organ maturation, both of which are required to translate embryonic potential into biologic reality. Many of the congenital defects encountered in the practice of pediatric surgery have their beginnings in some developmental miscue during the embryonic period that prevents normal growth and maturation during the fetal period. At birth, the consequences of these antecedent events often are manifested by serious physiologic derangements.

Fetal maldevelopment is complicated frequently by prematurity, that is, entry into the extrauterine world before fetal growth and maturation have been completed. Most fetal growth and organ maturation occur in the third trimester, and so premature birth interrupts development at a time when the rate of biologic change is most rapid. In many cases, prematurity is the direct consequence of intrauterine developmental abnormalities, such as those that produce polyhydramnios (excess amniotic fluid that results in increased uterine size and early labor). In others, prematurity occurs in an otherwise normal fetus and is the result of maternal factors. In both cases, prematurity causes significant morbidity by forcing the neonate to contend with extrauterine challenges using physiologic systems that are not yet prepared to do so and also forces the neonate to complete simultaneously a schedule of preprogrammed fetal tasks.

Although the “normal” gestational period is generally agreed to be 40 weeks, infants are considered to be full term at 37 weeks. Neonates born before 37 weeks are referred to as

premature or preterm. A normal-term birthweight is defined as 2,500 g or more. Infants born at less than 2,500 g are considered to be low birthweight, regardless of gestational age. More precise classifications include moderately low birthweight (1,500 to 2,500 g), very low birthweight (1,000 to 1,500 g), and extremely low birthweight (<1,000 g).

Mortality rates are directly related to both gestational age and birthweight. The current thresholds for survival appear to be approximately 22 weeks' gestation and 350 g birthweight. Above this threshold, survival rates increase rapidly, achieving 50% survival at approximately 24 to 25 weeks' gestation and 700 g.¹ Three additional independent variables predict increased survival in premature infants: female gender, exposure to corticosteroids in utero, and singleton gestation.² Continued gains in survival have come at an increasingly high cost of long-term morbidity. The most common types of serious long-term morbidity resulting from prematurity are neurodevelopmental conditions (e.g., cerebral palsy, mental retardation, seizure disorders), retinopathy, and chronic lung disease.

Although virtually all premature infants are born at low birthweights, a distinction is drawn between those whose weights are appropriate for their gestational age and those who are small for gestational age (SGA). SGA infants are defined as those in the 10th percentile or less with respect to age-adjusted birthweight. Normal intrauterine growth is a sensitive indicator of fetal well-being. Infants who qualify as SGA, whether term or preterm, are presumed to have experienced some intrauterine event that has compromised development. This phenomenon, referred to as intrauterine growth retardation (IUGR), can be caused by a plethora of factors that either reduce oxygen and nutrient delivery to the fetus or result in their decreased utilization. These abnormalities include maternal factors (tobacco, alcohol, and drug use; malnutrition; systemic disease), fetal factors (congenital defects, genetic or chromosomal anomalies), and placental factors (vascular anomalies, placental infarction, placental separation).

Both prematurity and IUGR may have detrimental consequences for the newborn. Both groups are challenged by insufficient energy reserves, poor thermal insulation, and increased heat and water loss. The premature infant must confront the extrauterine world with physiologically immature organ systems but may have a good eventual outcome if properly supported. Prenatal development may have been otherwise normal but prematurely terminated by maternal factors. On the other hand, the full-term SGA infant may have functionally mature organ systems and not require extensive physiologic support. When IUGR is the result of maternal or placental factors, premature birth separates the fetus from those factors and often results in compensatory growth and a good prognosis. When IUGR results from fetal or genetic factors, however, a poor prognosis may be anticipated. In general, an SGA infant has a better prognosis than a premature infant of the same birthweight because physiologic immaturity is less pronounced in the former.³

The rapid somatic growth and maturation occurring during the last trimester continues into the postnatal period and accounts for many of the unique metabolic events and nutritional requirements of the newborn surgical patient. This explosive growth phase is regulated largely by growth hormone (GH) and its peptide intermediates insulinlike growth factor-1 (IGF-1) and -2 (IGF-2), IGF-binding proteins (IGFBPs), and glucocorticoids, and is also influenced by insulin and thyroid hormone.^{4,5} Recently defined mediators of growth and metabolic activity such as leptin and ghrelin have also been implicated in fetal and neonatal growth. Ghrelin, a 28-amino-acid peptide produced by the stomach, placenta, and intestinal tract, stimulates the release of GH.^{6,7} In neonates, ghrelin has a potent orexigenic (appetite-stimulating) effect, and has been shown to be active in fetuses. It may play a role in prenatal programming and behavioral activities such as sucking and swallowing in preparation for postnatal feeding.⁸ Ghrelin levels peak in late infancy and decline to puberty, coinciding with the rapid growth rate that characterizes

early childhood.⁸ Leptin, a hormone produced by adipocytes, also appears to regulate the metabolic rate and substrate utilization in fetuses and neonates. Leptin is detected in the fetal circulation and, like ghrelin, stimulates the secretion of GH. The widespread abundance of leptin receptors in fetal tissues, especially in developing cartilage and bone, has led to the suggestion that leptin is involved in the control of growth in accordance with nutrient availability in utero.^{9,10} In adults, leptin plays an important role in the control of appetite and energy expenditure.

The normal-term baby will nearly double its birthweight by 4 months of age and will triple it by 1 year. The near-exponential rate of growth declines gradually thereafter until late adolescence. This pattern of growth is so constant in normal infants that significant departures from it are commonly the earliest indication of previously unrecognized disease. Any metabolic stress contributed by an acute disease or injury event will therefore be superimposed on the existing stringent demands for energy substrates.

As the neonate transitions to later infancy, childhood, and adolescence, its metabolic processes and responses gradually approximate those of the adult. As this transition represents a continuum, no clear delineation between these stages can be made. It is reasonable, however, to consider the metabolic responses of the neonate to starvation and stress as being qualitatively different from those of the adult, whereas those of older infants and children should be considered as only quantitatively different.

Basic Patterns of Energy Metabolism

In general, two basic patterns of energy metabolism are recognized: anabolic and catabolic. Anabolic processes characterize growth and involve the consolidation of nutrient substrates into structural and storage molecules. Catabolic processes involve the breakdown and redistribution of preexisting reserves to meet the short-term needs of specific tissues for specific substrates. Although persistent catabolism is pathologic and ultimately fatal, short-term catabolism is a necessary adaptive response to both starvation and stress.

The endocrine and cytokine environments that promote these two states are likewise distinct. Anabolic metabolism is mediated principally by insulin, IGF-1, and growth hormone. These mediators promote conversion of circulating glucose into glycogen (glycogenesis), storage of excess carbohydrate as fat (lipogenesis), and synthesis of new structural proteins from amino acids. The presence of available substrate and the absence of physiologic stress elicit a neuroendocrine environment conducive to these processes.

Catabolic metabolism is mediated by "counterregulatory" cytokines and hormones that have effects that are diametrically opposed to the anabolic mediators. These agents include tumor necrosis factor, interleukins, glucagon, cortisol, and catecholamines. These mediators promote an increase in glucose availability through hepatic glycogenolysis and gluconeogenesis and by inhibition of the peripheral effects of insulin on target organs. The objective of short-term catabolism is to generate adequate substrate for critical glucose-obligate tissues such as the brain, red and white blood cells, and renal medulla. The fetal and newborn heart depends on carbohydrates as a primary energy source and contains high concentrations of stored glycogen, allowing anaerobic glycolysis.¹¹ In contrast, oxidation of free fatty acids provides the main substrate for the myocardial metabolism in the adult heart.

Gluconeogenesis requires a supply of three-carbon fragments that reenter the glycolytic pathway under conditions that favor the reverse flow of intermediates and the synthesis of glucose. These three-carbon fragments are supplied by amino acids from protein breakdown (especially alanine and glutamine) and by glycerol from the hydrolysis of triglycerides. An additional source of gluconeogenic substrate is the Cori

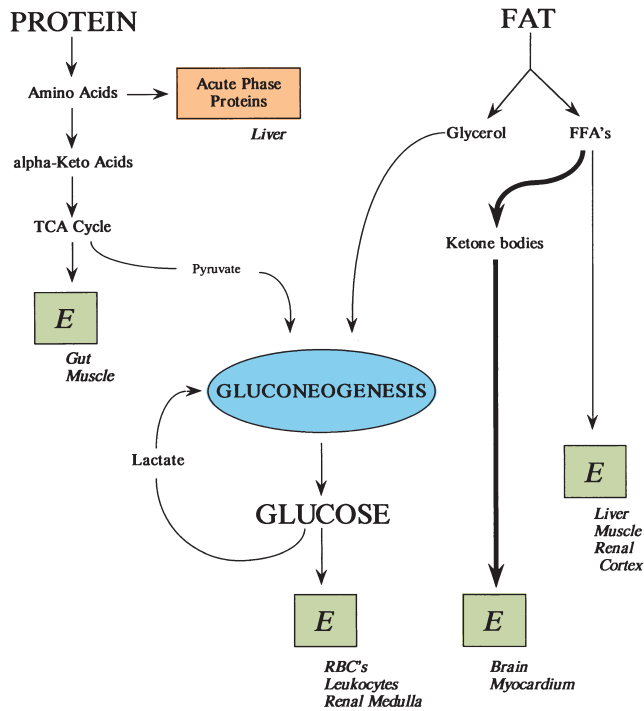

FIGURE 103.1. Energy production (E) during simple starvation. Ketoadaptation by brain and other glucose-obligate tissues allows free fatty acids (FFAs) to be used for energy production and limits the requirement for protein catabolism to generate gluconeogenic precursors via the tricarboxylic acid (TCA) cycle. (Adapted from Magnuson DK, Maier RV. In: Eichelberger MR, ed. *Pediatric Trauma: Prevention, Acute Care, Rehabilitation*. St. Louis, MO: Mosby; 1993.)

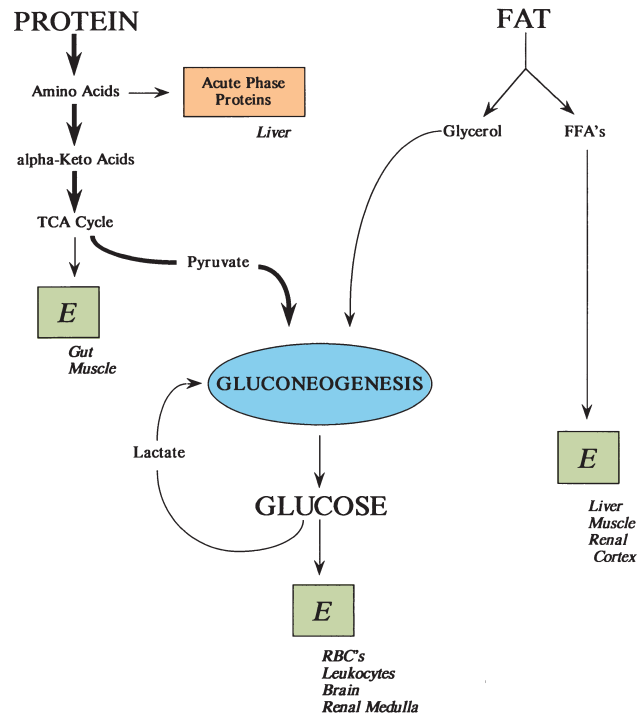

FIGURE 103.2. Energy production (E) during stress catabolism. Inhibition of ketoadaptation results in persistent protein catabolism to produce gluconeogenic precursors for glucose-obligate tissues. (Adapted from Magnuson DK, Maier RV. In: Eichelberger MR, ed. *Pediatric Trauma: Prevention, Acute Care, Rehabilitation*. St. Louis, MO: Mosby; 1993.)

cycle, in which lactate from anaerobic metabolism in compromised tissues (e.g., surgical or traumatic wounds) is transported to the liver and converted to pyruvate, a substrate for gluconeogenesis.

Catabolic metabolism can be separated into two distinct patterns: simple starvation and the stress response. In simple starvation, the brain (which accounts for the greatest demand for glucose) undergoes a gradual process called ketoadaptation, in which receptors and enzymes are expressed that allow for the utilization of ketone bodies as fuel (Fig. 103.1). Fatty acid metabolism then is altered to allow for the diversion of some fatty acids away from oxidative energy production and into the production of ketone bodies. The increased production of ketone bodies (ketogenesis), and their utilization by brain and myocardium, gradually reduces the demand for glucose and the degradation of visceral protein to gluconeogenic precursors.

In stress metabolism, however, the transition to the chronic starvation response of ketoadaptation is inhibited, and an ongoing requirement for glucose drives the continued breakdown of proteins to amino acids. Most of the amino acids produced by proteolysis during stress catabolism are rechanneled into gluconeogenesis (Fig. 103.2). The remainder is used in the synthesis of acute-phase proteins, in the synthesis of structural proteins for tissue repair, and for direct energy production by conversion to α -keto acids and entry into the tricarboxylic acid cycle. The mechanism of this inhibition is not well defined but most likely involves the persistence of stress-related neuroendocrine and cytokine mediators.

Metabolic Patterns in Neonates

- 2 The fetus utilizes glucose as its primary energy substrate. Transplacental movement of glucose by facilitated diffusion

maintains fetal glucose levels at about 75% of maternal levels. At birth, the neonate experiences an abrupt withdrawal of placental support and plasma glucose levels fall. In response to hypoglycemia, secretion of catecholamines, cortisol, and glucagon mediates a shift to acute stress metabolism, relying initially on glycogenolysis because the capacity for gluconeogenesis is markedly decreased in newborns. During the third trimester of pregnancy, glucose is stored as glycogen in the fetal liver and in small quantities in the skeletal muscle, kidneys, and intestine. The hepatic glycogen stores are limited in the neonate, and available glycogen reserves are depleted within 2 to 3 hours. Thereafter, gluconeogenesis is the sole supply of endogenous glucose until feeding provides new substrate. Protein and triglyceride breakdown provide direct energy substrates and gluconeogenic precursors, but fetal adipose and muscle mass are relatively modest, and this endogenous supply of fuel is also soon depleted. At this point, plasma glucose levels of 40 to 50 mg/dL are expected. As the infant begins to feed, absorption of exogenous substrates reverses the catabolic pattern, and an anabolic phase mediated by insulin begins. Plasma glucose levels usually rebound to 70 to 80 mg/dL by 3 days of age.

Neonatal demand for exogenous glucose is therefore immediate, and the provision of enteral or parenteral glucose soon after birth is critical. Not only does the neonate have a higher relative energy demand than older children and adults, but also a much greater proportion of the total caloric demand is generated by glucose-obligate tissues, and the availability of endogenous glucose from glycogen and gluconeogenesis is limited. Furthermore, fat stores and lipolytic pathways are both poorly developed at birth, requiring more metabolically versatile tissues to utilize glucose as well.

The metabolic priorities of the premature or SGA infant are identical to those of the full-term neonate, but relative deficiencies in substrate stores and immaturity of the counterregulatory

response to hypoglycemia make the preterm infant even more vulnerable to the risks of starvation and critical hypoglycemia. The time between birth and access to exogenous glucose tolerated by the preterm infant is inversely proportional to the degree of prematurity and may be measured in minutes instead of hours in extreme cases. In fact, one of the most striking differences between the normal-term infant and the preterm or SGA infant is the increased risk for hypoglycemic crisis in the latter: 50% in infants who are both premature and SGA.

Several factors contribute to this added vulnerability. Glycogen synthetase-b activity increases steadily in the last trimester. Preterm infants have restricted ability for gluconeogenesis from glycerol owing to decreased levels of glucose-6-phosphatase. In addition, the gluconeogenesis from amino acids or lactate is limited by lack of phosphoenolpyruvate carboxykinase activity. At 36 weeks' gestation, hepatic glycogen stores are only 30% of term levels; most glycogen deposition occurs after 36 weeks. Glycogen storage is therefore even more limited in preterm infants than in term infants, whose stores are depleted in a few hours. Additionally, skeletal muscle and fat constitute about 1% of body weight in a 1,000-g premature newborn, compared with about 15% in term infants, and so reserves of alternative energy substrates and gluconeogenic precursors are more limited as well. The ability to carry out β -oxidation of fatty acids and to produce ketone bodies also is depressed more severely in premature infants.¹² Ketogenesis is impaired even when they are given an exogenous source of lipid.

Thermoregulation

Temperature governs the kinetics of complex biochemical processes that have evolved to be maximally efficient within a narrow temperature range. Regulation of core body temperature has a high priority in the metabolic activities of the neonate and is a significant contributor to energy consumption. **3** The fetal environment is one of thermal constancy: maternal and placental mechanisms maintain an optimal temperature for fetal development and obviate the need for fetal energy expenditure to regulate temperature. In fact, the net heat produced by fetal metabolic activity must be transferred away from the fetal environment to avoid a rise in temperature.

Thermal equilibrium is a balance between heat production and heat loss. Newborns, particularly premature newborns, are characterized both by diminished capacity for heat production and by increased vulnerability to heat loss compared with older children and adults. The surface area-to-volume ratio of the neonate is greater than that of older patients, and so the area across which heat can be lost is disproportionately large compared with the mass of metabolically active tissue-generating energy. The body surface area-to-mass ratio averages approximately 250 cm²/kg in the adult and may be as high as 1,400 cm²/kg in the premature infant.¹³ The paucity of insulating fat and the lower muscular activity level contribute to the problem.

Heat loss in the neonate occurs chiefly through four mechanisms. Conduction refers to the transfer of heat by direct contact with another static heat acceptor. The rate and direction of heat flow depend on the heat gradient and the heat capacities of the two objects. Convection refers to the transfer of heat from the skin surface to a fluid, such as air, which carries heat energy away from the body. Radiation is the loss of heat as electromagnetic energy in the infrared spectrum. Evaporation of water at the skin surface consumes heat energy by transforming water from its liquid into gas state.

The physical environment surrounding the sick neonate provides limitless opportunities for heat loss. Contact with cold surfaces, particularly wet sheets and blankets, is a principal cause of heat loss. The flow of cold air over exposed skin surfaces transfers heat by both convection and evaporation. Evaporation is exacerbated by radiant warmers and phototherapy

lights. Premature infants with nonkeratinized epidermis are particularly susceptible to transepithelial water loss and may lose as much as 120 mL/kg of water each day. Evaporation consumes about 0.6 kcal/mL of water, which results in a metabolic cost of about 3 kcal/h. Means of reducing heat loss include using thermoneutral incubators and radiant warmers, removing wet blankets and towels in contact with the skin, and covering the infant with impermeable barriers to evaporation.

Heat production is a consequence of the thermodynamic inefficiency of chemical reactions; wasted energy is dissipated as heat. Basal heat production normally results from both metabolic processes and muscular work. Two additional mechanisms have evolved to provide heat energy when basal heat production is insufficient to maintain thermal stability: shivering and nonshivering thermogenesis. The temperature threshold for initiating thermogenesis in adults is 26°C to 28°C, but it ranges from 32°C in term newborns to 35°C in preterm infants.

Shivering thermogenesis is the production of heat by rapid, cyclical skeletal muscle contractions. The heat produced as a byproduct of this muscular "work" is transferred to blood circulating through the muscles and is redistributed throughout the body. Shivering thermogenesis is the major heat production mechanism in older infants, children, and adults.

Nonshivering thermogenesis is a process unique to the neonate and depends on the presence of brown adipose tissue (BAT). BAT is a unique tissue that is found transiently in the cervical, shoulder, axillary, and retroperitoneal regions of the neonate, and it is distinguished by its ability to generate metabolic heat by the inefficient metabolism of fatty acids. BAT is well established by 22 weeks' gestation. Sympathetic activation by cold stress causes norepinephrine to be released in BAT, bind to β -adrenergic receptors on adipocyte membranes, and initiate the hydrolysis of fatty acids. This process is facilitated by the presence of thyroid hormone. The fatty acids are shuttled into mitochondria where β -oxidation takes place. Normally, fatty acid oxidation is coupled to the phosphorylation of adenosine diphosphate (ADP) to adenosine triphosphate (ATP), preserving potential energy in the high-energy phosphate bond. In brown adipocytes, however, a unique peptide called uncoupling protein 1 (UCP1) "uncouples" the oxidative phosphorylation of ADP, allowing energy liberated by oxidation to be released as heat. The high density of mitochondria present in brown adipocytes attests to its role in heat production. Leptin also modulates UCP1, suggesting that BAT may play a role in overall energy balance regulation in infants.¹⁴

Nonshivering thermogenesis is the principal means of heat production in neonates, but it has severe limitations. It is a costly means of producing heat from a metabolic standpoint and rapidly depletes precious energy stores in term infants. Premature and SGA infants, with relatively reduced fat composition, are poorly equipped to use this strategy effectively. In term neonates, BAT constitutes about 10% of body fat and is gradually replaced by white adipose tissue in later infancy. Neonates who undergo surgery under general anesthesia run a high risk of hypothermia due not only to environmental exposure, but also to the inhibitory effects of general anesthetic agents on neonatal nonshivering thermoregulation.^{15,16}

NUTRITIONAL SUPPORT

Energy Requirements

4 Neonates and children have significantly higher energy requirements than adults. These requirements diminish gradually throughout childhood, but they do not reach adult levels until physical maturity is attained. The two principal reasons for this discrepancy are a higher basal metabolic rate (BMR) and an additional energy requirement for growth. The total energy expenditure (TEE) consists of the BMR, the energy

TABLE 103.1**AGE-SPECIFIC ENERGY REQUIREMENTS**

■ AGE (y)	■ ENERGY REQUIREMENT (kcal/kg/d)
0–1	120–90
1–7	90–75
7–12	75–60
12–18	60–30
>18	30

required to process substrates, energy for activity, energy for thermoregulation, and the energy cost of growth. The resting energy expenditure (REE), which may be substituted for BMR, is estimated to be 45 to 50 kcal/kg per day in term neonates and 50 to 60 kcal/kg daily in premature infants.^{17,18} This compares with an REE of 20 to 25 kcal/kg daily in adolescents and adults.

Neonates and infants expend a much higher percentage of their total energy production on somatic growth than do older children. Growth consumes 35% to 40% of an infant's caloric intake during the first 6 months of life, a value that declines to about 5% at 2 years of age.¹⁹ The energy cost of growth, which includes the energy used in new tissue synthesis plus the energy content of the synthesized tissue, approximates 40 to 50 kcal/kg daily in the neonate and progressively less in the older child. Add to these the energy requirements for nutrient processing, cold stress, and activity, and the baseline energy requirements for a term neonate are about 100 to 110 kcal/kg daily. The preterm neonate may require 120 kcal/kg per day or more to sustain growth. Caloric requirements for intravenous nutrition are perhaps 10% less because of the absence of obligate energy loss in fecal output.

The energy requirements of older infants and children gradually approach adult levels of 30 to 35 kcal/kg daily as BMR, cold stress, and rate of growth all decline with age (Table 103.1). This downward trend is moderated somewhat by an increase in energy expended in physical activity. Although many methods of estimating caloric requirements exist, the most straightforward estimation simply uses a weight-based calculation of caloric needs (Table 103.2).

It is important to recognize that these guidelines represent estimates for unstressed children. Energy requirements are altered in a variety of clinical settings commonly encountered in pediatric surgical patients. Both congenital heart disease and pulmonary disease can be associated with reduced pulmonary compliance and increased work of breathing, which can substantially increase energy expenditure. The healing of wounds related to major surgical procedures, trauma, and burns also increases caloric requirements. Sepsis, pancreatitis, and other conditions associated with generalized inflammatory activation may increase energy requirements dramatically.

TABLE 103.2**WEIGHT-SPECIFIC ENERGY REQUIREMENTS**

■ WEIGHT (kg)	■ ENERGY REQUIREMENT (kcal/d)
0–10	100/kg
10–20	1,000 + 50/kg over 10
>20	1,500 + 20/kg over 20

It is equally important to appreciate that, in certain circumstances, caloric requirements in stressed children may be decreased because of changes in REE and the energy consumption related to growth. As opposed to older children and adults, infants actually may experience a decrease in REE during periods of postsurgical stress.^{20,21} As previously discussed, the metabolic pattern that characterizes acute stress states is one of catabolism and growth postponement. This temporary growth inhibition is a consequence of, among other things, a cytokine and neuroendocrine environment that opposes the anabolic actions of insulin. Because 30% to 40% of a healthy neonate's caloric requirement represents energy required for growth, administration of the same caloric load to the stressed infant or child may result in significant overfeeding. The complications of overfeeding are not commonly recognized but include fluid overload, hepatic steatosis, and increased lipogenesis. Lipogenesis is associated with increased CO₂ production and is reflected in an increased respiratory quotient. Increased CO₂ production requires an increase in minute ventilation that may not be tolerated by critically ill neonates and children with respiratory disease and limited ventilatory reserve.

In the stressed infant or child, therefore, it may be prudent to reduce caloric administration transiently by as much as 25% to 30% during the acute stress phase, when growth is inhibited and the metabolic rate depressed. Determining when the metabolic environment has reverted back to one more permissive for growth and caloric utilization can be difficult. Direct calculation of the respiratory quotient by indirect calorimetry and measurement of nitrogen balance may be helpful in detecting a capacity to utilize more energy substrate. More frequently, however, a clinical judgment must be based on resolution of the hyperdynamic response to adrenergic stimulation or infection and the restoration of normal hemodynamics and fluid requirements.

Substrate Requirements

Carbohydrates. Carbohydrates constitute the major source of energy substrate for infants and older children, although they have a lower caloric density (3.4 kcal/g of intravenous hydrated dextrose, 4 kcal/g of enteral glucose) than either proteins (4 kcal/g) or fats (9 kcal/g). As discussed, glucose is the preferred fuel in a variety of tissues, including brain and blood cells. The obligate glucose consumption rate in neonates is about 4 to 6 mg/kg per minute. This compares with a glucose utilization rate of about 1 mg/kg per minute in adults. The discrepancy is explained in part by the fact that the neonatal brain accounts for 10% of body weight in the newborn and only 2% of body weight in adults. This contrast is even more striking in SGA infants whose brain growth is preserved in the face of generalized IUGR. In these infants, brain size and glucose consumption are even more disproportionately large. Most of the demand for glucose in newborns is for brain energy production, with relatively little remaining available for other tissues. Consequently, prolonged hypoglycemia may cause profound neurologic impairment.

The addition of small amounts of glucose to intravenous fluids prevents protein catabolism by providing a fuel source for glucose-obligate tissues and obviating gluconeogenesis. In adults, this protein-sparing glucose requirement is about 1 mg/kg per minute and is conveniently provided by administering 5% dextrose in water (D₅W) intravenously at maintenance fluid rates. In neonates, who require 4 to 6 mg/kg per minute of glucose to avoid protein catabolism, it is usually necessary to administer maintenance intravenous fluids as 10% dextrose in water (D₁₀W). The relatively higher fluid administration rate and dextrose concentration provide the increased glucose supply necessary to avert protein catabolism in the short term.

Normal plasma glucose values are variable and depend on gestational age, weight, and postnatal age. The definition of

hypoglycemia is therefore somewhat fluid, but it is generally agreed that plasma glucose levels less than 35 mg/dL in term infants and less than 25 mg/dL in preterm infants constitute metabolic emergencies and require immediate intervention. Healthy full-term infants of appropriate birthweight rarely develop hypoglycemia. Infants at risk for hypoglycemia include those who are premature, SGA infants, multiple gestations, infants of diabetic mothers, infants of toxemic mothers, and infants who are critically ill for some other reason. Neurologic injury resulting from an inadequate supply of substrate to brain cells depends on both the degree and duration of hypoglycemia. Signs of hypoglycemia are late and nonspecific and include poor feeding, respiratory irregularity, apnea, bradycardia, hypothermia, cyanosis, irritability, tremors, seizures, lethargy, hypotonia, and coma.

Mild, asymptomatic hypoglycemia usually can be managed simply by initiating early oral feedings with breast milk or D₁₀W. Severe or symptomatic hypoglycemia requires intravenous dextrose administration. Dextrose concentrations of 10% to 12.5% are the maximum that can be tolerated by peripheral veins; higher concentrations of dextrose require a central (e.g., umbilical) venous catheter. Treatment consists of administering glucose at a rate of 6 to 8 mg/kg per minute (3.6 to 4.8 mL/kg per hour of D₁₀W). Profoundly hypoglycemic infants may require an initial dextrose “minibolus” of 200 mg/kg (2 mL/kg D₁₀W) over 1 to 2 minutes. The dextrose infusion rate then is increased by 2 mg/kg per minute every 3 to 4 hours until stable plasma glucose levels of 40 to 50 mg/dL are achieved.

Most neonatal hypoglycemia is transient, allowing dextrose administration to be weaned down as feeding or intravenous nutritional support is begun. Persistent hypoglycemia, particularly in infants requiring more than 12 to 15 mg/kg per minute of dextrose, may indicate a pathologic cause for hypoglycemia. Causes of pathologic hypoglycemia in neonates include hyperinsulinism (Beckwith-Wiedemann syndrome, nesidioblastosis or islet cell dysmaturity syndrome), congenital adrenal insufficiency, and other inborn errors of metabolism. In these circumstances, treatment options include corticosteroids, glucagon, epinephrine, somatostatin analogues, diazoxide, calcium channel blockade, intramuscular growth hormone, and near-total pancreatectomy.²²

Fats. Lipids are the other main source of energy substrate. Nutrient lipids consist primarily of triglycerides—a glycerol backbone to which three fatty acids are esterified. During energy metabolism, the fatty acids are cleaved off the glycerol moiety and transported into mitochondria, where they undergo β -oxidation to produce energy stored in ATP. In addition to providing an energy source of high caloric density (9 kcal/g), lipids are essential for cell membrane structure, steroid hormones, the synthesis of inflammatory mediators such as prostaglandins and leukotrienes, and thermal insulation.

Most dietary triglycerides contain long-chain fatty acids 16 to 18 carbons long. Most fatty acids derived from animal sources have no double bonds within the carbon chain (saturated), whereas those derived from fish and vegetables have one or more double bonds (unsaturated). Because most fatty acids can be synthesized from carbohydrate precursors, there is no absolute dietary requirement for most fats as long as adequate calories are being provided from sugars. The fatty acids linoleic and α -linolenic acids are considered to be “essential” from a dietary standpoint because they cannot be synthesized *de novo*. α -Linolenic acid is a “triene” characterized by three double bonds in its carbon chain. Linolenic acid deficiency has been associated with neurologic dysfunction, which suggests a role in brain development. Linoleic acid has two double carbon bonds, but is converted into arachidonic acid, which contains four double bonds and is therefore a “tetraene.” Linoleic acid deficiency is marked by dryness and thickening of the skin, hair loss, and delayed wound healing.

An increased triene-to-tetraene ratio indicates essential fatty acid deficiency.

Proteins. Although amino acids can be converted to their keto acid counterparts, enter the tricarboxylic acid cycle, and yield usable energy (4 kcal/g), they are ideally reserved for the synthesis of new structural and functional proteins. The need for protein precursors is particularly acute in the neonate who is undergoing accelerated somatic growth. As the infant ages and the rate of growth declines, the requirements for dietary protein diminish somewhat. Recommendations for protein requirements in infants and children are variable. Premature infants may require 3 to 4 g/kg each day, whereas term newborns require 2 to 3 g/kg each day, older infants 1.5 to 2 g/kg per day, and children and adolescents 1 to 1.5 g/kg daily. These recommendations are somewhat controversial given that healthy newborn infants on a breast milk diet maintain normal growth with an average protein intake of 1.5 to 2 g/kg daily.

Eight of the 20 amino acids are unable to be produced by enzymatic conversion of other existing amino acids and therefore must be obtained from dietary sources. These essential amino acids are threonine, leucine, isoleucine, valine, lysine, methionine, phenylalanine, and tryptophan. Several other amino acids may be considered essential in the neonate because the specific enzyme systems for their conversion are consistently slow to mature in the postnatal period. These include histidine, tyrosine, cysteine, taurine, and possibly proline. Although clinical consequences of deficiencies in these amino acids have not been clearly defined, amino acid formulations designed for administration to adults may not contain them (especially cysteine and taurine), and specialized pediatric formulations supplemented with these amino acids are available.

Although not usually considered an essential amino acid, glutamine is of critical importance to many tissues and has been the subject of intense investigation.²³ Glutamine is produced from glutamate by the enzyme glutamine synthetase and has many physiologic functions. It participates in nitrogen transport in both the ammonia and urea cycles. It serves as a precursor for nucleic acid synthesis and an energy source in tissues with rapid cell proliferation. Intestinal epithelium is the primary consumer of glutamine, extracting a significant fraction from the circulation as well as the intestinal lumen. Within the continuously dividing enterocytes, glutamine is a necessary precursor to nucleic acid synthesis as well as the principal energy substrate. Maintenance of mucosal health and barrier function is directly dependent on the availability of glutamine for enterocyte metabolism.

Because glutamine synthetase is present in both infants and adults, and because glutamine is unstable in solution, this amino acid is not included in commercial amino acid formulations. During episodes of physiologic and metabolic stress, glutamine levels may fall despite the intravenous administration of other amino acids, suggesting a stress-induced alteration in glutamine synthesis. Intestinal mucosal atrophy and loss of barrier function may occur during prolonged periods of intestinal rest when only parenteral nutrition is administered. The addition of glutamine modified to increase stability in standard intravenous amino acid formulations and enteral administration of glutamine-containing formulas are being investigated as strategies for improving mucosal function and promoting intestinal growth in infants and children with severe gut injury.

Types of Nutritional Support

Enteral Support. The provision of all fluids, electrolytes, and substrates through the gastrointestinal tract is the ultimate goal of nutritional therapy. Using the gastrointestinal tract, even if only for a fraction of the patient's needs, provides trophic substances and enteroendocrine stimulation for intestinal growth and development, maintains the integrity of intestinal barrier

function, and mitigates against the cholestatic liver complications of prolonged gut rest. Enteral feeding is associated with significantly fewer complications than parenteral nutrition and can be administered at a much lower cost. Equally important, early oral feeding is crucial for the maintenance of an intact suck and swallow reflex and the prevention of behavioral feeding aversion.

- 5 Breast milk is the optimal nutritional vehicle. Human milk is a complex mixture of macromolecules that evolves over time as the growing infant's needs change. The usable energy content of milk is divided almost equally between carbohydrates and lipids. The carbohydrate fraction is predominately lactose, but it includes more than 100 other oligosaccharides that have putative immunologic functions. A variety of lipids constitute the fat component, including both linoleic and linolenic acids. The protein content of human milk is relatively low compared with cow's milk and commercial formulas. As opposed to cow's milk, human milk has more whey than casein. The whey fraction includes many proteins, some with antibacterial functions, including the lactalbumins, albumin, lactoferrin, lysozyme, secretory immunoglobulin A (IgA), enzymes, growth factors, and hormones. In addition to these macromolecules, human milk contains a variety of cellular elements, including B and T lymphocytes, macrophages, and neutrophils.

When human breast milk is not available, a wide variety of commercial formulations are available from which to choose (Table 103.3). The nutritional compositions of these formulas are modeled on breast milk, but they differ with respect to the specific carbohydrate, protein, and fat content. Commercial formulas contain slightly more protein and less fat as a percentage of total calories than breast milk. Considerable variation in the specific nutritional components provides multiple options for optimizing nutrition in neonates with gastrointestinal derangements.

Most of the available formulas have a caloric density equal to that of human milk: 20 kcal/oz (0.67 kcal/mL). Formulas with higher caloric densities are available for infants with restrictions on fluid intake, or may be provided by fortifying standard formulas with polymeric glucose or other additives. Children between 6 months and 1 year of age may be transitioned to pediatric formulas with a higher caloric density of 30 kcal/oz.

The amount of formula required to supply adequate energy substrate to the growing infant can be estimated easily. Assuming an energy requirement of 110 kcal/kg daily, a feeding regimen of eight feedings per day, and a caloric density of 20 kcal/30 mL, the calculation of the required feeding volume can be reduced to a single "nutritional coefficient" of 22:

$$\text{Wt (kg)} \times 22 = \text{Volume of breast milk or formula required every 3 h}$$

This coefficient reduces to 7.3 for 24-hour continuous drip feedings.

A number of specialized formulas are available for infants with specific abnormalities of substrate absorption. The most important carbohydrate source for infants is lactose, the predominant disaccharide in human milk, which is hydrolyzed by intestinal lactase to glucose and galactose. Lactase and other disaccharidases are sensitive to changes in the villous environment and exhibit reduced activity in the setting of mucosal disease. Lactase is the most labile of brush-border enzymes, being among the first to exhibit decreased activity in disease and the last to increase during recovery. Inflammatory disorders that cause increased epithelial turnover result in a population of immature enterocytes with reduced lactase activity. Prolonged gut rest also results in reduced disaccharidase activity as a result of villous atrophy and mucosal loss.

Premature infants have reduced intestinal brush-border enzyme activity as a result of epithelial immaturity, especially with respect to lactase, but they also have deficiencies in fat and protein absorption for the same reason. Premature-specific

formulas provide carbohydrates largely as glucose polymers (corn syrup) with or without lactose. They also provide a fat mixture of long-chain and medium-chain triglycerides to improve fat absorption. In the extremely premature or stressed infant, formulations providing hydrolyzed proteins (oligopeptides) have advantages over those that contain complex, intact proteins. Formulas for premature infants also provide increased concentrations of various other components, such as calcium and phosphorous, to meet the needs of accelerated bone mineralization (a fetal task under normal circumstances).

Hypersensitivity to bovine protein antigens may cause inflammation of the gastrointestinal tract and malabsorption in some infants. Soy-based formulas are usually the initial option for infants with cow's milk protein allergy because the protein content derives exclusively from soy proteins. As many as 30% of these infants will develop hypersensitivity to soy proteins as well and may require the use of a formula containing only protein hydrosylates, which are less allergenic than intact proteins.

Synthetic medium-chain triglycerides (MCTs) containing fatty acid moieties 8 to 10 carbons long are commercially available and have some advantages over long-chain triglycerides in certain clinical settings. MCTs are efficiently metabolized in the gut lumen to their constituent parts, are readily absorbed, and produce a nearly identical caloric yield. More importantly, they appear to have the capability of being transported directly into the enterocyte without prior degradation to glycerol and fatty acid. Hence, they offer the advantage of improved absorption in prematurity and other conditions that impair lipid digestion. These states include biliary obstruction (e.g., biliary atresia), bile salt insufficiency (e.g., ileal resection), pancreatic insufficiency (e.g., cystic fibrosis), and decreased absorptive surface area (e.g., short-gut syndrome). Because they bypass lymphatic absorption, they also may be useful in reducing lymphatic flow in treating chylous ascites and chylothorax. Because MCTs do not contain the essential fatty acids, periodic supplementation is necessary to avoid deficiency states.

Total Parenteral Nutrition. Few developments in clinical medicine have had a more profound impact on the survival of premature and critically ill neonates than the capability of administering hypertonic solutions of nutritional substrates by central venous catheter. The management of total parenteral nutrition (TPN) is complicated and covered more thoroughly elsewhere. Several issues related specifically to the management of TPN in infants and children are discussed here.

Indications for TPN depend on age, size, and clinical condition. In general, the younger the patient, the more intolerant he or she is of the effects of prolonged fasting. Although a healthy child may tolerate a week of inadequate nutrition or longer, infants and neonates are not so resilient. It is reasonable to consider initiating TPN in any neonate expected to fast for at least 2 to 3 days. Extremely premature neonates with multiple medical problems are commonly started on TPN within the first 2 days of life. Substrate concentrations are initially low and are gradually weaned up to calculated maintenance values over several days to avoid hyperglycemia and acidosis.

Estimations of caloric needs are made using the same assumptions discussed in the previous section. It is reasonable to divide total caloric requirements between carbohydrates and fats. The energy content of proteins should not be calculated to contribute to caloric requirements because the exogenous amino acids are expected to be used primarily for new protein synthesis. The appropriate distribution of calories between carbohydrates and fats may differ between individual patients, but in general fats should account for 40% to 50% of nonprotein calories, and carbohydrates usually account for 50% to 60%. Carbohydrates are administered as dextrose, and standard lipid emulsions containing essential fatty acids also are used. Although essential fatty acids can be supplied in adequate quantities with once-weekly lipid infusions, the high caloric density and low respiratory quotient characteristic of

intravenous lipids make them attractive as a primary energy source for most neonates who may have difficulty handling large fluid and CO₂ loads.

Protein requirements in parenteral nutrition are age dependent because of the changing requirements for somatic growth. As discussed previously, premature infants typically require 3 to 4 g/kg daily, whereas term newborns require 2 to 3 g/kg daily, and older infants 1.5 to 2 g/kg daily. To promote efficient utilization of amino acids for protein synthetic purposes, the nonprotein calorie-to-nitrogen ratio should be 150:1 to 200:1. Special formulations, including amino acids thought to be essential specifically in neonates, are widely available. Pediatric requirements for electrolytes, fat- and water-soluble vitamins, and trace elements must be provided as well.

The administration of both enteral and parenteral nutrition involves many assumptions and estimations. One of the most important aspects of nutritional management, then, is monitoring the response to therapy. In the older child and adolescent, maintenance of weight is an important goal. In the rapidly growing neonate, measurable nonedema weight gain is the objective. A daily weight gain of about 0.5% to 1% is a reasonable goal (15 to 30 g daily in the average term neonate). Measurements of white blood count, serum albumin, prealbumin and its binding proteins, and transferrin are helpful in assessing protein synthetic status in the neonate, just as they are in the adult. Routine surveillance of serum electrolytes, plasma and urine glucose, and liver function studies are mandatory to recognize metabolic complications of TPN administration.

FLUID, ELECTROLYTE, AND RENAL PHYSIOLOGY

Fluid Compartments

Like the adult, but to a greater degree, the infant and child are composed primarily of water. This simple fact influences many clinical phenomena, ranging from fluid balance to the volume of distribution for electrolytes and drugs. The percentage of body weight that is water, as well as its distribution within physiologic compartments, is in a state of rapid flux during the fetal and neonatal period. Body fluid distribution approaches a steady state by approximately 1 year of age and remains reasonably constant thereafter.

- 6 The greatest changes in total body water (TBW) occur during fetal development. At 12 weeks' gestation, water constitutes

95% of fetal mass. This percentage declines to about 80% by 32 weeks' gestation and to 75% at term. Prematurity results in the birth of a fetus at a stage of rapid change in water content, a fact that needs to be appreciated when caring for the preterm surgical patient. A further decline in TBW occurs in a roughly linear fashion over the first year of life and reaches a plateau of about 65% by 1 year of age (Fig. 103.3).

Within the body, water is distributed between two main compartments: intracellular and extracellular. Although the extracellular compartment predominates early in fetal life, continued cellular proliferation and growth cause the intracellular and extracellular compartments to approach equivalence (about 40% each) at term. Postnatal diuresis of extracellular fluid causes the extracellular compartment to be reduced further within the first few weeks. Continued growth and fat deposition cause extracellular fluid to decline to about 25% at 1 year of age, whereas at the same time the intracellular compartment rises to a plateau of 40% to 45%.

The extracellular compartment is divided further into the interstitial and intravascular compartments. Generally, intravascular water accounts for only 25% of extracellular water, but this value is highly variable and depends on changeable factors, such as hematocrit and oncotic pressure. Blood volume itself is relatively high in the fetus because it includes blood circulating in the umbilical-placental vessels. At term, the normal fetal blood volume after cord occlusion is about 90 mL/kg (higher in premature infants). Blood volume declines gradually to 80 mL/kg in toddlers, 75 mL/kg in school-aged children, and 65 mL/kg in adolescents.

Fetal stress is often accompanied by the generalized accumulation of extracellular fluid, a condition referred to as hydrops fetalis. Fluid accumulates both as soft tissue edema and as effusions in the peritoneal, pleural, and pericardial spaces. This condition is readily diagnosed by prenatal ultrasound, which can detect cavitory fluid accumulations and quantify soft tissue edema by measuring the increased thickness of cervical soft tissues between the spine and the skin (nuchal thickening).

The mechanism of fluid accumulation is ill defined but most likely involves hydrostatic forces related to in utero congestive heart failure and venous hypertension. A principal cause of hydrops fetalis is autoimmune hemolytic anemia secondary to maternal-fetal Rh antigen incompatibility (erythroblastosis fetalis). The high fetal oxygen demand continues in the face of ongoing red cell destruction, resulting in a compensatory increase in cardiac output and the eventual development of high-output cardiac failure. Other causes of hydrops fetalis

FIGURE 103.3. Changes in total body water distribution during prenatal and postnatal growth and development. (Adapted from Friis-Hansen B. Changes in body water compartments during growth. *Acta Paediatr* 1957;46[suppl 110]:1.)

also involve congestive heart failure: fetal arrhythmias, structural heart defects, mediastinal shift resulting from diaphragmatic hernia or developmental lung anomalies, and arterial “steal” syndromes caused by fetal tumors such as giant sacrococcygeal teratomas and hemangiomas. Additional causes are generalized infections, conditions of reduced oncotic pressure due to liver disease or nephropathies, maternal substance abuse, or chromosomal abnormalities.

These causes of fetal extracellular fluid accumulation are referred to as nonimmune hydrops and carry a poor prognosis. About 80% of fetuses identified with this condition die in utero, and only half of those that are liveborn survive beyond the neonatal period.

Renal Physiology

Maintenance of water and electrolyte balance within the body's fluid compartments is the responsibility of the kidneys. Renal function in infants and children relies on the same physiologic principles as adults, but it differs in the relative capacities to excrete and conserve water and solutes. These differences mainly affect infants and small children; by the age of 2 years, a child's renal function approaches that of the adult.

Renal function depends on two interrelated processes: the glomerular ultrafiltration of plasma and the tubular modification of the ultrafiltrate by selective reabsorption of water and solutes. Glomerular filtration is a passive event in which water and low-molecular-weight solutes percolate through the glomerular capillary membrane into the glomerular lumen. About 20% of renal plasma flow is filtered through the glomeruli in this fashion. The glomerular filtration rate (GFR) is dependent on renal blood flow, which is autoregulated by a tubuloglomerular feedback mechanism between specialized renal tubular cells (macula densa) and proximal arterioles. Modification of the ultrafiltrate occurs in the tubular system and collecting ducts through active transport of some solutes and passive diffusion of water and other solutes. A detailed description of these physiologic events is beyond the scope of this chapter, but certain generalizations can be made regarding age-related differences in renal function.

Urine output in the immediate postnatal period is characterized by three distinct phases: prediuretic, diuretic, and postdiuretic. The prediuretic phase occupies the first 24 hours and is marked by a fixed, low urine output of 1 mL/kg per hour or less. Urine output during the second and third day of life increases dramatically, to 5 to 10 mL/kg per hour, and is largely insensitive to exogenous fluid administration. Much of the rapid reduction in TBW seen in the postnatal period occurs during this diuretic phase. The unloading of excess water has an extremely high priority and is observed even in premature infants.²⁴ Beginning on the fourth day of life, urine output begins to display an appropriate responsiveness to fluid balance.

Renal blood flow (RBF) and GFR are both markedly reduced in the neonate because of elevated renovascular resistance. In the newborn, RBF represents only 6% of cardiac output, compared with 25% in the older child and adult. As resistance falls, RBF increases by fourfold in the first 3 months and doubles again to adult levels (indexed to body surface area) by 1 or 2 years of age. Changes in GFR correspond roughly to those in RBF. Because of this preexisting diminished RBF and GFR and the delicate balance between vasoconstrictive and vasodilatory forces, neonates are highly susceptible to the development of renal insufficiency under certain circumstances. Both acute tubular necrosis (ATN) and vasomotor nephropathy (VMNP) can occur secondary to reductions in renal perfusion because of hypovolemia, hypotension, sepsis, neonatal asphyxia, and administration of indomethacin and angiotensin-converting enzyme inhibitors. Treatment mainstays include optimization of intravascular volume, dopamine administration for infants with congestive heart failure, and

furosemide administration in infants with indomethacin-induced ATN.²⁵

Tubular function also varies according to age. The ability to concentrate urine is dependent on mechanisms that cause reabsorption of free water in renal collecting ducts to regulate serum osmolarity. Free water absorption is governed by the actions of antidiuretic hormone (ADH), which is secreted by the posterior pituitary in response to increased serum osmolarity and decreased blood pressure, and which acts on tubular epithelium in the collecting ducts to increase permeability to water. Water diffuses out of the ductal lumen and into the interstitium and capillary network, as directed by the concentration gradient.

Although the capacity to produce ADH is fully developed both in preterm and term infants, the sensitivity of tubular epithelium to ADH appears to be diminished in all neonates. The mechanism for reduced sensitivity appears to be related to the diminished production and increased degradation of prostaglandin E₂. On stimulation by ADH, renal collecting duct cells increase the expression of aquaporin-2 transmembrane water channels, increasing the translocation of water from the collecting duct lumen to the interstitium. The expression of aquaporin-2 in neonates is diminished as well.²⁶ These differences account for the fact that infants have a reduced capability to excrete concentrated urine relative to adults. The neonatal kidney can concentrate urine to a maximum of 500 to 600 mOsm/L. By 1 year of age, maximum concentrating capacity reaches about 1,000 mOsm/L, and by 2 years of age, the concentrating capacity attains adult levels of 1,200 to 1,400 mOsm/L. In contrast, the ability of the neonate to excrete free water and to produce dilute urine appears to exceed that of the adult. Maximal urine dilution capacity in the preterm and term neonate is about 30 to 50 mOsm/L, compared with 70 to 100 mOsm/L in the adult.

The other primary tubular function is the regulation of sodium balance, which in turn determines TBW and affects intravascular volume. Sodium regulation is governed largely by two counterregulatory hormones: aldosterone and atrial natriuretic peptide (ANP). Aldosterone is secreted by the adrenal cortex in response to activation of the renin-angiotensin system, and it acts on renal tubular epithelium to increase active sodium resorption and passive water resorption. Active sodium resorption is tightly coupled to potassium excretion. ANP is secreted in response to atrial distention and increased levels of ADH, catecholamines, and corticosteroids, and it promotes increased sodium excretion and water diuresis through enhanced GFR and reduced sodium resorption.

Both of these systems appear to be active in the neonate. The term infant is able to conserve sodium effectively, like the adult, but it appears to be less effective in excreting an excess sodium load. In contrast, the preterm infant is a “salt waster,” and demonstrates a marked inability to conserve sodium in the face of sodium restriction. Additionally, because sodium excretion occurs at an increased but relatively fixed rate in preterm infants, these patients are unable to excrete a sodium load by increasing sodium clearance beyond the preprogrammed rate. This relative inability to regulate sodium excretion makes the neonate particularly susceptible to changes in intravascular and extravascular volume resulting from inappropriate fluid management.

Sodium handling can be expressed in terms of the fractional excretion of sodium (FE_{Na}) or the percentage of sodium filtered that is actually excreted in the urine. Calculation of FE_{Na} requires measurement of plasma (P) and urine (U) concentrations of both sodium (Na) and creatinine (Cr) (sodium excretion is indexed to creatinine excretion because creatinine is not reabsorbed):

$$FE_{Na} \% = (U_{Na})(P_{Cr}) / (U_{Cr})(P_{Na}) \times 100$$

Under normal circumstances, the FE_{Na} for both term infants and adults is 1% or less. Premature infants normally

have elevated FE_{Na} values of 3% to 9%. Calculation of the FE_{Na} can be helpful in assessing the cause of oliguria by determining whether renal tubular function indicates increased sodium resorption. Recent diuretic use invalidates the FE_{Na} as an indicator of tubular function. Oliguria associated with an appropriately low FE_{Na} implies renal hypoperfusion. Oliguria associated with an abnormally high FE_{Na} (>1 in term infants, >3 in preterm infants) indicates inappropriate sodium excretion and suggests a renal parenchymal cause for the oliguria (e.g., ischemic acute tubular necrosis).

Fluid and Electrolyte Management

Neonates and young children are exquisitely sensitive to small changes in body chemistry and do not have mature homeostatic mechanisms to compensate for rapid changes in fluid and electrolyte flux and to maintain internal balance. Additionally, the requirements for chemical homeostasis in the neonate are superimposed on a background of ongoing change. Iatrogenic alterations of body chemistry in the child are therefore quickly and easily produced by inattention to the details of fluid and electrolyte administration, causing impairments of cardiovascular, pulmonary, neurologic, and gastrointestinal function.

The systematic approach to fluid and electrolyte management requires an estimate of maintenance requirements, which then are adjusted to take into account both preexisting imbalances and ongoing losses. Once therapy is initiated, frequent reassessment and readjustment are necessary to ensure that the patient is responding as initially predicted. This involves documenting reversal of the symptoms and signs of dehydration, correction of any electrolyte or acid-base abnormalities, and normalization of urine output.

When normal renal function is present, the most reliable and easily measured indicator of adequate hydration is urine output. In the adult, the production of urinary output at a rate of 0.5 mL/kg per hour (30 to 40 mL/h) is adequate to excrete a normal renal solute load, given the concentrating capacity of the adult kidney. Because the immature kidney has diminished concentrating capacity compared with that of the adult, and because the pediatric solute load requiring excretion is relatively higher owing to the increased requirements for energy metabolism and growth, normal urinary outputs in children are higher. A desirable urine output in preterm infants is 3 to 4 mL/kg per hour, dropping to 2 mL/kg per hour in neonates and infants, and 1 mL/kg per hour in toddlers and school-age children.

Maintenance Requirements

Maintenance fluid and electrolyte requirements are those required to replenish normal, anticipated losses. Obligate fluid losses can be estimated by considering water lost in the excretion of solutes in the urine, excretion of stool, transepithelial water and sweat lost by evaporation, water lost through respiration, water utilized in anabolic metabolism for growth, and water gained through oxidation of nutrient substrates. Obviously, the actual "maintenance" fluid requirements in individual patients will vary widely according to the variables listed, but certain generalizations can be helpful in estimating requirements and initiating therapy.

Maintenance fluid requirements are related primarily to patient size and can be estimated by the Holliday-Segar method (Table 103.4). Many neonates, however, will require much higher maintenance fluid volumes (100 to 150 mL/kg daily) as a result of increased obligatory losses from a variety of causes. Increased transepithelial losses occur with fever, with the use of radiant warmers, with exposure to phototherapy for hyperbilirubinemia, and in premature infants with thin, nonkeratinized skin. Neonates with tachypnea or those undergoing mechanical ventilation may have increased lung

TABLE 103.4

HOLLIDAY-SEGAR METHOD FOR ESTIMATING FLUID REQUIREMENTS

■ WEIGHT (kg)	■ FLUID REQUIREMENT (mL/d)
0–10	100/kg
10–20	1,000 + 50/kg over 10
>20	1,500 + 20/kg over 20

water loss despite inspired gas humidification. It is common practice to reduce the fluid volumes for the first 2 to 3 days of life to about 70% of maintenance to accommodate the obligatory diuresis of extracellular fluid.

Maintenance requirements of sodium are about 2 to 3 mEq/kg daily in term infants and children. This value may be somewhat higher in premature infants who cannot conserve sodium as effectively. Potassium requirements are also approximately 2 mEq/kg daily. Requirements for exogenous calcium are low in older infants and children with adequate skeletal stores, but calcium supplementation may be necessary in the premature infant with little skeletal ossification, particularly in those with cardiac disease, and in all children receiving prolonged TPN. As discussed in the preceding section, glucose is administered along with maintenance fluids to provide sufficient caloric support to meet the needs of glucose-obligate tissues and to prevent protein catabolism for gluconeogenesis.

Taking these requirements into consideration, maintenance fluids composed of one-fourth normal saline in 10% dextrose ($D_{10}1/4NaCl$) should be appropriate for most healthy neonates. Half-normal saline in 10% dextrose may be required in the premature infant. After the infant transitions into the postnatal diuretic phase on the second or third day of life, 10 to 20 mEq/L of KCl may be added to replenish obligate potassium losses and avoid hypokalemia. Depending on prior nutritional status and ongoing illness, it may be appropriate to reduce glucose intake to 5% dextrose after 1 to 2 weeks.

Preexisting Imbalances

Frequently, maintenance fluid administration must be superimposed on a significant preexisting deficit or excess. A complete history and physical examination are invaluable in detecting evidence of fluid imbalance and understanding its cause. Protracted vomiting or diarrhea, copious enterostomal output, chronic diuretic therapy, mechanical ventilation, phototherapy, and the like are all clues to extraordinary fluid losses. Physical examination is paramount in assessing current fluid status in all children. Because of the absence of comorbidity in most cases, physical signs of volume status are frequently more reliable in children than in adults.

Signs of both intravascular and extravascular fluid imbalance should be sought. Signs of extravascular fluid deficit, which are apparent with mild to moderate dehydration ($<10\%$), include poor skin turgor, recessed eyes, sunken or soft fontanel, dry mucous membranes, absence of tears, and orthostatic hypotension and tachycardia. Signs of intravascular fluid deficit, which usually indicate more severe dehydration ($>10\%$), include resting tachycardia and hypotension, oliguria, delayed capillary refill, reduced extremity temperature, diminished peripheral pulses, and altered mental status.

Signs of intravascular volume depletion usually indicate a need for intravenous resuscitation, which is usually initiated before proceeding with maintenance therapy. Isotonic crystalloid resuscitation with serial boluses of lactated Ringer solution (10 to 20 mL/kg) is usually appropriate and followed by

careful assessment of the response to therapy. For dehydration associated with hyponatremia and hypochloremia, normal saline boluses may be preferable. In most conditions, however, repeated boluses of saline may be associated with iatrogenic hypernatremia and a normal anion gap metabolic acidosis resulting from hyperchloremia with a compensatory decrease in serum bicarbonate anion.

Preexisting fluid excesses are encountered less frequently in children, but it is important to recognize them to avoid exacerbating the underlying condition by instituting ill-advised maintenance therapy. Fluid excesses occur most frequently as a result of iatrogenic mismanagement, but they also may be seen in acute renal failure and congestive heart failure. Signs may include peripheral and pulmonary edema, hypertension, and increased heart size on chest radiography. Obviously, maintenance therapy may need to be postponed until euvolemia is achieved through diuresis.

Ongoing Losses: Body Secretion Compositions

Before a final strategy can be established, it is important to anticipate and account for the presence of extraordinary ongoing fluid losses. These losses usually result from increased gastrointestinal losses caused by nasogastric suction, enterostomal output, diarrhea, pancreatic or biliary drainage, or drainage of chylous ascites or chylothorax. Another common, although “occult” cause of ongoing fluid loss is the unavoidable sequestration of extracellular fluid in regions of surgical, inflammatory, or traumatic injury, often referred to as third spacing.

Because gastrointestinal secretions from various levels of the gastrointestinal tract have differing electrolyte profiles, they are most safely replaced on an equal volume (mL per mL) basis with fluid of similar composition. This can be accomplished by periodically measuring the electrolyte composition of the lost fluid or by estimating the composition according to known values (Table 103.5). In practice, upper gastrointestinal secretions in the setting of paralytic ileus or mechanical obstruction frequently approach isotonicity and may be safely replaced with lactated Ringer solution as long as careful monitoring of serum electrolytes is maintained. Pancreatic, biliary, and some ileostomy-related fluids are safely replaced with 0.45% NaCl supplemented with sodium bicarbonate at a concentration of 25 to 50 mEq/L. Chylous drainage may require

the addition of albumin to avoid a progressive decrease in serum oncotic pressure over time. Third-space losses are best replaced with lactated Ringer solution administered by intermittent bolus (10 to 20 mL/kg), because the exact rate of fluid loss is not measurable and adequacy of resuscitation can be judged best by physiologic response.

Specific Examples

Abnormalities of Sodium Concentration. Changes in serum sodium concentration reflect changes in free water balance. Mild hyponatremia (serum sodium of 125 to 135 mEq/L) is a common electrolyte abnormality in children and is seen frequently in postoperative patients with excessive ADH secretion in response to perceived intravascular volume depletion. It is also seen in patients with chronic conditions associated with fluid retention, such as cirrhosis, nephrotic syndrome, and congestive heart failure. Severe, acute hyponatremia (serum sodium <120 mEq/L) usually is associated with volume contraction from hypertonic fluid loss, as can occur with vomiting, diarrhea, excessive stomal output, or inappropriate ADH secretion (SIADH).

Acute hyponatremia can cause severe neurologic symptoms, including headache, nausea, vomiting, lethargy, seizure activity, and coma. These symptoms are referred to as water intoxication and result from diffusion of water into relatively hypertonic brain cells, causing cerebral edema and intracranial hypertension. Treatment of severe or symptomatic hyponatremia involves correction of the underlying cause and administration of hypertonic saline (3% NaCl) over 30 to 60 minutes to correct serum sodium to about 125 mEq/L, followed by a more gradual elevation of serum sodium levels to normal over the ensuing 24 to 48 hours. The sodium deficit can be calculated by using a volume of distribution for sodium of 0.6:

$$\text{Sodium deficit} = [\text{Na}^+_{\text{target}} - \text{Na}^+_{\text{measured}}] \times \text{weight (kg)} \times 0.6$$

Hyponatremia of a more chronic, gradual nature should be corrected more slowly, particularly if asymptomatic. When hyponatremia develops gradually, compensatory loss of osmotic agents from brain cells prevents water intoxication. Rapid normalization of serum sodium levels may therefore cause a rapid fluid shift out of compensated brain cells, occasionally causing permanent neurologic injury. This is referred to as *osmotic demyelination* or *central pontine myelinolysis*, although demyelination often is diffuse and not necessarily involving the

TABLE 103.5

COMPOSITION OF BODY FLUIDS

LR, lactated Ringer solution.

pons. Osmotic demyelination can manifest as quadriplegia or pseudobulbar palsy. Mild, chronic hyponatremia in conditions associated with fluid retention usually can be corrected with free water restriction alone.

Hypernatremia is an uncommon electrolyte abnormality in children. Neurologic symptoms are related to brain-cell dehydration and shrinkage, causing disruption of bridging veins and intracranial hemorrhage. Recommendations for correction include calculation of the free water deficit and slow correction with D₅W over 24 to 48 hours. As a result of the production of cytoplasmic osmotic substances (ideogenic osmoles) by brain cells to offset increased extracellular sodium concentration, chronic hypernatremia is usually well tolerated and should be corrected gradually to avoid precipitating acute cerebral edema.

Abnormalities of Acid–Base Status. Metabolic acidosis can be categorized as having an increased anion gap or normal anion gap. The causes of an increased anion gap metabolic acidosis in children are the same as in adults: lactic acidosis or ketoacidosis accounts for most cases. Their implications and management in children do not differ from that in the adult. Normal anion gap metabolic acidosis, however, is much more common in infants than in older children and adults. The immature kidney is less efficient both at bicarbonate reclamation in the proximal tubule and at hydrogen ion excretion in the distal tubule. These functional deficits are considered a transient form of renal tubular acidosis type II (proximal), which is one of a heterogeneous group of disorders characterized by abnormal hydrogen ion and bicarbonate handling in the nephron. The vast majority of neonates outgrow this condition in the first year of life.

One of the most commonly encountered acid–base abnormalities in infants is metabolic alkalosis associated with hypochloremia, hypokalemia, and volume contraction. This pattern is typical of that seen in infants with protracted vomiting resulting from hypertrophic pyloric stenosis. Persistent vomiting of acidic gastric secretions causes the progressive depletion of both hydrogen and chloride ions. The loss of hydrogen ions results in alkalosis. Hypochloremia is associated with an increase in serum bicarbonate ion to maintain electroneutrality and with a decrease in renal hydrogen ion excretion. Renal tubular sodium resorption increases to reverse extracellular volume contraction. Sodium resorption is coupled with excretion of potassium. This potassium loss is facilitated by systemic alkalosis, which drives hydrogen ions out of renal tubular cells in exchange for potassium, raising renal tubular availability of potassium. As potassium becomes progressively depleted, a shift to hydrogen excretion occurs, resulting in the creation of urine with an inappropriately low pH: paradoxical aciduria. Treatment is directed at restoring extracellular fluid volume and chloride and potassium ions, and correcting the underlying pathology.

RESPIRATORY PHYSIOLOGY AND SUPPORT

Pulmonary Development

Abnormal or incomplete pulmonary development accounts for much of the clinical pathophysiology observed in infants with respiratory distress syndrome, bronchopulmonary dysplasia, and pulmonary hypoplasia related to congenital diaphragmatic hernia or cystic adenomatoid malformation. All these conditions manifest physiologic disturbances related to immature or altered development of the tracheobronchial tree, pulmonary vasculature, or alveolar parenchyma. A general knowledge of normal lung development is therefore necessary to understand these pathologic entities and their management.

Normal lung development can be described as occurring in roughly five phases. The embryonic phase begins in the third

week of gestation, when a ventral diverticulum appears in the proximal foregut. This lung bud grows caudally, undergoing a series of binary branchings to form first the carina and then the lobar and segmental bronchi. The developing lung buds are composed of entodermal cells destined to become both bronchial epithelium and alveolar parenchyma. As the primitive lung bud branches, it grows into mesoderm destined to differentiate into cartilage, smooth muscle, and vascular structures. This phase is largely complete by 6 weeks.

The pseudoglandular phase extends from week 7 to week 16 and is characterized by continued dichotomous branching of the primitive airways. Under normal conditions, the developing airway branches about 23 times and acquires a glandular appearance as the epithelial tubes are surrounded by amorphous mesenchymal tissue. Entodermal differentiation into bronchial and alveolar epithelium occurs, as does mesenchymal differentiation into muscle, blood vessels, and connective tissue. Physical contact between the entodermal and mesodermal components is necessary for reciprocal induction of differentiation. By the end of this phase, all tracheobronchial branching is complete.

The canalicular phase extends from week 17 to 24 and is characterized by development of the gas-exchange architecture of the lung parenchyma. Primitive epithelial channels evolve into more complex groupings, interstitial tissue diminishes, and capillary ingrowth occurs. Alveolar epithelial cells differentiate into type I and II pneumocytes. Type I pneumocytes make up the alveolar wall and have a flattened morphology with scant cytoplasm, which is appropriate for the diffusion interface between the alveolar lumen and the capillary blood. Type II pneumocytes contain cytoplasmic lamellar bodies that identify these cells as future surfactant producers. A considerable body of evidence suggests that type I pneumocytes differentiate from existing type II pneumocytes. The earliest time at which functional gas exchange is possible is at the end of the canalicular phase.

The terminal sacular phase follows the canalicular phase at 24 weeks and lasts until the end of gestation. Two principal events occur during this time: (a) further morphologic change in the gas-exchange units with thinning of the interstitium and increased exposure of capillaries to the epithelial interface and (b) production of surfactant in preparation for extrauterine life. At this stage, each capillary is exposed to only one respiratory surface.

At birth, each lung contains approximately 20 million immature gas-exchange units, referred to as terminal sacs. In the postnatal alveolar phase, these structures proliferate and mature, reaching 300 million mature alveoli by the time the child is 8 years old. The terminal sacs multiply in number and mature morphologically. During this final phase, the respiratory membrane thins out further and presents more surface area to the capillary network. In the mature alveolus, each capillary is exposed simultaneously to at least two alveolar surfaces. After the end of this phase, when the child is 8 years of age, further lung growth occurs only by increasing individual alveolar size.

Apoptosis, the process of programmed cell death without inflammation, plays an important role in both prenatal and postnatal lung development. As the airway epithelium proliferates into the mesenchyme, apoptosis is involved in the formation of branch points. As the airways develop further, mesenchymal apoptosis is necessary for the thinning out of the interstitial connective tissue and the creation of the blood–alveolar interface. Apoptosis is also involved in the consolidation of the microvascular network into a single capillary layer between alveoli. Apoptosis in the developing lung appears to be upregulated by transforming growth factor- β and insulinlike growth factor and downregulated by nitric oxide.²⁷ Apoptosis combined with selective local morphogenesis forms the developing lung. Local expression of fibroblast growth factor-10 (FGF-10) seems to induce the latter.²⁸

Lung growth during prenatal development appears to be linked to the secretion of fetal lung liquid. Fetal breathing movements provide for amniotic fluid flow into and out of the

FIGURE 103.4. Lung volumes and capacities. (Adapted from Wilson JM, DiFiore JW. In: O'Neill JA, Rowe MI, Grosfeld JL, et al., eds. *Pediatric Surgery*, 5th ed. St. Louis, MO: Mosby; 1998.)

developing lungs. Net fluid flow appears to be outward, however, implying that lung fluid is secreted into the airway and flows out during the fetal respiratory cycle. Lung liquid production seems to stimulate lung growth, perhaps by providing a positive distending pressure in the fluid-filled fetal lung. The mechanism by which physical distention leads to cell proliferation or apoptosis is referred to as mechanotransduction. This process appears to depend on cell deformation and changes in cell-cell and cell-matrix adhesion, which are transduced into cytoskeletal changes and activation of intracellular kinases.

Pulmonary Physiology in the Neonate

Lung Volumes. Total lung capacity is composed of four distinct lung volumes: tidal volume, inspiratory and expiratory reserve volumes, and residual volume (Fig. 103.4). Residual volume is the volume of gas left in the lung after complete, forced expiration. The sum of the three lung volumes above residual volume (expiratory reserve, tidal, and inspiratory reserve) is the vital capacity, or the maximal volume of gas that can be voluntarily inspired or expired. Two functional parameters with great relevance to the physiologic management of lung pathophysiology are the functional residual capacity (FRC), which is the total volume of gas remaining in the lung after passive expiration during tidal breathing when alveolar pressure has equilibrated to atmospheric pressure, and the closing capacity (CC), which is the volume below which small conducting airways and alveoli begin to collapse.

Alterations in FRC occur in many pathologic states and significantly impact the efficiency of gas exchange. Normally, FRC exceeds CC, and alveoli in most regions of the lung remain open for gas exchange during tidal breathing. In disease states in which FRC is reduced, usually because of diminished compliance, FRC may drop below CC, causing regional atelectasis and impaired gas exchange. Common conditions associated with reduced FRC include respiratory distress syndrome (RDS), adult respiratory distress syndrome (ARDS), cardiogenic pulmonary edema, pneumonia, and postoperative hypoventilation caused by pain and splinting. Management focuses on recruiting collapsed alveoli by restoring and maintaining a higher FRC. This usually entails applying positive intra-alveolar distending pressure in the form of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP).

Mechanical Properties and Their Effects on Ventilation.

The bulk flow of gas can be described by the simple equation:

$$\Delta P = VR$$

where ΔP is the pressure gradient, V is volume flow per unit time, and R is resistance. The mechanical properties that govern clinically important aspects of lung ventilation include compliance, elastic recoil, and airway resistance. Compliance describes the distensibility of lung tissue and reflects the energy required to effect a volume change. Compliance is defined as the change in lung volume per unit change in pressure: $\Delta V/\Delta P$, with higher values signifying greater distensibility. Dynamic compliance (C_{dyn}) uses peak inspiratory pressure (PIP) in the calculation, whereas static compliance (C_{st}) uses plateau inspiratory pressure; hence, C_{dyn} is always lower than C_{st} . From a clinical standpoint, compliance is a critical determinant of lung volume, which in turn determines the efficiency of ventilation/perfusion matching and gas exchange. Conditions that reduce compliance make it more difficult to maintain volumes above closing capacity and therefore promote atelectasis. Low compliance states are caused by increased structural wall tension (edema or fibrosis), increased alveolar surface tension (surfactant deficiency), or decreased alveolar radius (reduced FRC).

Compliance is the inverse of elastic recoil, defined as the tendency for stretched tissue to return to its prestretched state. Whereas elastic recoil depends in part on intrinsic properties of lung and chest-wall tissue structure, the elastic recoil of lung parenchyma is closely related to alveolar wall tension. Wall tension tends to cause collapse of the alveolus unless opposed by some internal “splinting” pressure within the alveolus. The interaction between wall tension, alveolar radius, and pressure is defined by the Laplace relationship:

$$P = 2T/R$$

where P equals the splinting pressure, T the wall tension, and R the alveolar radius. This relationship states that the internal distending pressure required to counteract alveolar collapse is directly proportional to wall tension and inversely proportional to alveolar radius. At low alveolar radii (volumes), higher splinting pressures are required to counteract wall tension and oppose alveolar collapse. This explains both the tendency for low lung volumes to promote regional atelectasis and the high energy investment required to reopen collapsed alveoli. The most important component of total wall tension in the neonate is surface tension, which is the tension created by the physiochemical properties of the gas-liquid interface. In the mature lung, surface tension is dramatically reduced by surfactant, a phospholipoprotein that coats the alveolar surface and stabilizes it against collapse. Therefore, alveolar collapse is facilitated both by small lung volumes and by surfactant insufficiency.

The relationship between pressure and lung volume, referred to as the static compliance curve, is not linear (Fig. 103.5). At

FIGURE 103.5. Static compliance curve. Nonlinear relationship between inflation pressure and volume change illustrated at low, normal, and high functional residual capacities (FRCs). Volume represented as fraction of total lung capacity (TLC). (Adapted from Harris TR, Wood BR. In: Goldsmith JP, Karotkin EH, eds. *Assisted Ventilation of the Neonate*, 3rd ed. Philadelphia, PA: WB Saunders; 1996.)

low lung volumes, atelectatic alveoli initially require a large energy input to reopen. As more alveoli are recruited, further increases in pressure bring about much larger increases in lung volume. At high lung volumes, alveoli are overdistended and less compliant. Pulmonary management aims at maintaining FRC in the steep portion of the static compliance curve, where lung compliance is optimal.

Extrinsic compliance refers to the component of lung compliance related to extrapulmonary structures, primarily chest wall, diaphragm, and abdomen. Under normal circumstances, chest wall compliance in the infant is high and contributes little to total compliance, which then is determined mostly by intrinsic lung compliance. In some instances, such as increased chest-wall edema caused by sepsis, hydrops fetalis, persistent fetal circulation, or superior vena caval thrombosis, reduced extrinsic compliance can have a significant impact on total compliance and ventilation. Chest-wall compliance also can decrease with the use of intravenous fentanyl, which affects muscle tone. Extrinsic compliance also decreases when intra-abdominal pressures are increased (e.g., ileus, closure of abdominal wall defects), in the presence of pleural fluid collections, and after diaphragmatic plication or diaphragmatic hernia repair.²⁹

Ventilation is inversely related to resistance, which has both viscous and airway components. Viscous resistance is the friction generated by contiguous tissues moving against each other. It accounts for up to 40% of total resistance in neonates and is increased with conditions of high tissue density caused by edema (e.g., RDS, bronchopulmonary dysplasia, and anatomic left-to-right shunts). Airway resistance, on the other hand, reflects friction caused by gas molecules interacting with each other and with the airway walls.

Airway resistance is related to length, radius, turbulence, and density. According to Poiseuille's law, resistance is directly related to the length of the conducting tube and inversely related to the fourth power of radius:

$$\Delta P = V 8hL/pr^4$$

where h is viscosity, L is tube length, and r is radius. Radius is a powerful determinant of resistance in simple tubes, but in the branching bronchial tree, the impact of progressively smaller radii is offset by the large total cross-sectional area of the distal airways. This is particularly true for older children and

adults, in whom occult small-airway disease may exist without affecting total resistance. The small airways in infants contribute a much larger percentage of total airway resistance, however, so conditions affecting these airways, such as bronchospasm and bronchiolitis, have a more significant effect on airflow. Although tube length has few important clinical ramifications, it is interesting to note that infants with pulmonary hypoplasia resulting from congenital diaphragmatic hernia have truncated development of the bronchial tree and lower airway resistance than normal infants.³⁰

Turbulence refers to the random swirling of gas molecules during bulk flow, in contrast to laminar flow, which is characterized by organized streaming of gas molecules along the same axis. Turbulence is induced as flow rates increase, and it makes ventilation less efficient because it consumes energy. Gas density is directly and linearly related to resistance. Although this has little clinical relevance in most settings, the use of low-density gas mixtures improves ventilation with anatomic abnormalities that produce high resistance, such as tracheal stenosis and bronchopulmonary dysplasia. Heliox, a mixture of 80% helium and 20% oxygen, has a density one-third that of room air and therefore generates one-third the resistance.³¹

The calculated product of resistance and compliance is a useful parameter that integrates two of the primary determinants of airflow and is referred to as the time constant (TC):

$$TC = RC_{dyn}$$

where R is resistance and C_{dyn} is dynamic compliance. The time constant reflects the time required for pressure equilibration to occur as air flows down a pressure gradient. During one time constant, 63% of an inspiratory or expiratory tidal volume can occur, whereas about four time constants are required for completion of flow. Conditions that increase either resistance or compliance will increase the time constant. During mechanical ventilation, consideration of this effect is required to allow adequate expiratory time before initiation of the next ventilatory cycle. Inadequate expiratory time results in "breath stacking" and overdistention of alveoli. Additionally, most focal lung diseases result in considerable heterogeneity in regional time constants. Inspiratory times need to be adjusted to allow for the longest time constants to ensure even distribution of ventilation. Conditions associated with low compliance result in short time constants. Therefore, an increase in minute ventilation is accomplished more efficiently by increasing ventilatory rate, which is permitted by the short time constant, than by increasing tidal volume, which requires high pressures in low-compliance lungs.

Pulmonary Blood Flow. Although the pathophysiology of pulmonary hypertension is covered more thoroughly in the subsequent section, the basic principles governing the regulation of pulmonary vascular resistance and flow are introduced here because they determine the matching of ventilation and perfusion, and hence the efficiency of gas exchange. Blood flow in the lung is influenced by a variety of mechanical and vasoreactive phenomena, which combine to determine local vascular resistances and, therefore, the regional distribution of blood flow.

As discussed, resistance is inversely related to the fourth power of vessel radius, making vessel caliber the most important determinant of resistance and flow. Pulmonary vascular caliber is determined both by mechanical factors acting on vessel walls and by muscular contraction within vessel walls. The mechanical factors that influence vessel caliber include radial traction on larger vessels produced by parenchymal expansion and compressive pressure imparted on microvessels within the alveolar walls by air pressure within the alveolus.

These mechanical forces come into play primarily at the extremes of lung volume. At low lung volumes, the lack of radial traction reduces caliber and increases resistance within

the larger parenchymal vessels. At high volumes, excessive intra-alveolar pressures are imparted to the alveolar arterioles, capillaries, and venules as they transit through the alveolar unit. If this intra-alveolar pressure exceeds downstream pulmonary venous pressure (or pulmonary capillary wedge pressure), it becomes a determinant of the pressure gradient driving flow across the alveolar capillary. Normally, the pressure gradient is determined by the difference between mean pulmonary arterial pressure (P_{PA}) and pulmonary venous pressure (P_{PV}) ($\Delta P = P_{PA} - P_{PV}$). When alveolar pressure exceeds P_{PV} , it acts as the downstream pressure ($\Delta P = P_{PA} - P_{Alv}$). The anatomic arrangement of vessels “suspended” within the alveolar unit and influenced by external alveolar pressures is referred to as a Starling resistor. The phenomenon of the Starling resistor allows the lung to be viewed as a continuum of zones in which capillary blood flow depends on the relationship between hydrostatic venous pressure and intra-alveolar pressure.

In addition to mechanical forces, the distribution of blood flow within the pulmonary circulation is affected by a variety of vasoconstrictive stimuli. Extensive autoregulation of pulmonary blood flow ensures that perfusion is directed toward capillaries adjoining well-ventilated alveoli and away from collapsed or fluid-filled alveoli. This autoregulation is accomplished by increasing pulmonary vascular tone in vessels leading to poorly ventilated alveoli with low partial pressures of oxygen, a process referred to as hypoxic pulmonary vasoconstriction (HPV).

Factors that influence HPV include (a) the partial pressure of oxygen within the alveolus (PAO_2), (b) the partial pressure of oxygen within arteriolar blood (PaO_2), (c) the partial pressure of carbon dioxide in arteriolar blood ($PaCO_2$), and (d) the pH of arteriolar blood. Pulmonary vascular tone is inversely related to the partial pressure of oxygen in both the alveolus and the capillary blood, but PAO_2 appears to be a more important factor. In fact, alveolar hypoxia is the single most powerful stimulus to pulmonary vasoconstriction. The pH of capillary blood also affects blood flow; local acidosis is an important stimulus to pulmonary vasoconstriction. Increased $PaCO_2$ increases vascular tone both by lowering pH and by acidosis-independent mechanisms.

Physiologic mediators of vascular smooth muscle contraction common to these stimuli have not yet been fully identified. The caliber of pulmonary vessels at any given time is dependent on the balance of mediators causing vascular smooth muscle contraction and relaxation. Mediators of vasodilation include bradykinin, prostaglandins E_1 and A_1 (PGE_1 , PGA_1), prostacyclin (PGI_2), and nitric oxide. Mediators of vasoconstriction include the leukotrienes, endothelin-1 (ET-1), prostaglandin D_2 (PGD_2), and histamine. Histamine, ET-1, and PGD_2 appear to have biphasic effects mediated by different receptor populations, causing vasodilation in the fetal and early neonatal periods and vasoconstriction after the first few days of life.³²⁻³⁴ Most of these mediators originate from local sources, such as pulmonary endothelial cells and mast cells.

Gas-Exchange Determinants. The ultimate goal of respiratory function is gas exchange, which is the transfer of oxygen from inspired air to capillary blood and the reciprocal transfer of carbon dioxide from blood to alveolar gas. The principal determinants of gas exchange are total alveolar ventilation, ventilation/perfusion matching, diffusion, and extrapulmonary shunt. The mechanical properties discussed previously affect gas exchange primarily by determining the amount and distribution of ventilation. Regulation of pulmonary blood flow determines ventilation/perfusion matching and the efficiency of gas exchange. Extrapulmonary shunt occurs primarily through cardiac septal defects and the ductus arteriosus and is discussed in the section on cardiac physiology. Diffusion abnormalities are uncommon causes of gas-exchange problems in children. Total ventilation and ventilation/perfusion matching are the most important causes of impaired gas exchange and merit further discussion.

Ventilation

Tidal volume is divided into two separate volumes: alveolar ventilation, which participates in gas exchange, and physiologic dead space, which does not. Physiologic dead space is further divided into anatomic dead space, which describes the volume of the prealveolar conducting airways, and alveolar dead space, which includes the ventilated but nonperfused alveoli. Normally, alveolar dead space is negligible, and total physiologic dead space approximates one third of tidal volume. In some diseases, such as ARDS, alveolar dead space may be increased. During mechanical ventilation, anatomic dead space is increased by the addition of ventilator tubing. Effective alveolar ventilation is best monitored by measuring PCO_2 , which is relatively insensitive to abnormalities of ventilation/perfusion matching. Alveolar hypoventilation results in both inadequate oxygenation and inadequate carbon dioxide removal.

Ventilation/Perfusion Matching

The appropriate matching of ventilation and perfusion is the single most important determinant of gas exchange in the normal lung. Most disease states that cause abnormal gas exchange do so by promoting an imbalance between ventilation and perfusion. Perfusion is matched to regional ventilation by the mechanisms governing pulmonary blood flow discussed previously. When the normal mechanisms of pulmonary vascular autoregulation are impaired, ventilation/perfusion ratio (\dot{V}/\dot{Q}) mismatch ensues.

Normal alveoli with matched ventilation and perfusion are considered to have a \dot{V}/\dot{Q} ratio of 1. Those with relatively less ventilation have a \dot{V}/\dot{Q} less than 1, and those with relatively less perfusion have a \dot{V}/\dot{Q} greater than 1. Those with ventilation but no perfusion define alveolar dead space, whereas those with perfusion but no ventilation contribute to intrapulmonary shunt, which is microcirculatory bypass of alveolar exchange. Between these two extremes lies a spectrum of \dot{V}/\dot{Q} relationships that may contribute to abnormal gas exchange. \dot{V}/\dot{Q} mismatch generally results in hypoxemia with normocarbia. Because carbon dioxide diffuses through the capillary-alveolar interface much more readily than does oxygen, \dot{V}/\dot{Q} mismatch has relatively little effect on PCO_2 levels.

Mismatching of ventilation and perfusion is responsible for the hypoxemia encountered in most clinical settings. These include the disease states in which lung compliance is reduced, FRC drops below closing volume, and regional alveolar collapse occurs: pneumonitis, aspiration, RDS, ARDS, cardiogenic pulmonary edema, postoperative splinting, and others. Simply increasing forced inspiratory oxygen (FiO_2) does little to rectify the situation because the venous admixture of blood passing through low \dot{V}/\dot{Q} units remains low in oxygen saturation, and blood passing through normal \dot{V}/\dot{Q} units cannot further increase oxygen content to compensate. Therapeutic efforts must be directed at reopening closed alveoli and restoring homogenous alveolar ventilation.

Although diuresis, antibiotic therapy, and chest physiotherapy may have important roles in restoring FRC and matched ventilation and perfusion, perhaps the most effective therapeutic intervention is the use of continuous positive intra-alveolar distending pressure: CPAP or PEEP, which recruit and maintain previously closed or underventilated alveoli and improve \dot{V}/\dot{Q} matching and oxygenation. They also shift ventilation up on the static compliance curve, producing a higher tidal volume with less pressure trauma.

The use of positive-pressure mechanical ventilation and PEEP must be managed judiciously because they can have both beneficial and deleterious effects on \dot{V}/\dot{Q} matching. It is important to remember that positive airway pressure is transmitted to the alveolar capillaries that carry blood flow through the

alveolar network. The alveolar pressure surrounding these capillaries acts as a Starling resistor and can impede capillary blood flow if it exceeds downstream venous pressure. The use of high peak ventilatory pressures without the use of PEEP, or the excessive use of PEEP itself, can cause overdistention of alveoli, reduced compliance, increased alveolar capillary resistance, and diminished alveolar capillary perfusion. The result is redirection of blood flow to underventilated alveoli, which actually worsens \dot{V}/\dot{Q} mismatch. Similarly, the use of PEEP in focal lung disease may be counterproductive because its effects are preferentially directed to the normal, more compliant alveoli. This causes overdistention of normal \dot{V}/\dot{Q} units and redistribution of blood flow to diseased alveoli, canceling the benefits of hypoxic pulmonary vasoconstriction.

Surfactant and Respiratory Distress Syndromes

- 8** Respiratory distress syndrome, or hyaline membrane disease (HMD), is the most common cause of respiratory distress in neonates and one of the primary causes of neonatal mortality in developed countries. RDS occurs as a direct result of pulmonary immaturity and surfactant deficiency. Because surfactant is not produced and secreted by type II alveolar epithelial cells until the third trimester, prematurity causes newborns to rely on lungs of variable maturity to support extrauterine respiration. Preterm infants born during the terminal sacular phase of lung development face the challenge of supporting gas exchange with lungs characterized by relatively thicker epithelial barriers, suboptimal capillary architecture, and a tendency toward alveolar collapse. This last feature is the most important cause of respiratory failure in premature infants and is directly related to the lack of surfactant, which lowers surface tension at the alveolar liquid–gas interface.

Surfactant is a complex substance composed of phospholipids (80%), proteins (10%), and cholesterol (10%). The phospholipid profile changes during lung maturation, but phosphatidylcholine predominates and is the principal substance responsible for the surface tension–lowering properties of surfactant. Phosphatidylinositol is present in immature surfactant, but it is largely replaced by phosphatidylglycerol in mature lungs, a useful fact when assessing fetal lung maturity. Surfactant also contains at least four specific proteins: surfactant protein-A (SP-A), SP-B, SP-C, and SP-D. SP-A and SP-D are important in host lung defense, facilitating the uptake of bacterial and viral pathogens by local immune cells. SP-C participates in phospholipid layer formation in the alveolus. SP-B is critical for processing, storage, and secretion of surfactant from the type II pneumocytes. Genetic mutations that result in the absence of functional SP-B are lethal in the perinatal period.

The physiologic role of surfactant is to stabilize alveolar units against collapse and thereby to facilitate homogeneous lung ventilation and \dot{V}/\dot{Q} matching. LaPlace's law states that the pressure required to overcome the retracting force of surface tension in a sphere is inversely related to radius. In clinical terms, this means that smaller alveoli actually require greater distending pressure to maintain stability. This is analogous to the phenomenon one experiences when trying to inflate a balloon: the initial pressure required to begin inflation is high and becomes progressively less as the balloon radius increases. Because the lung is a collection of alveoli of varying sizes, and all alveoli are exposed to the same atmospheric pressure through a shared network of airways, the natural tendency is for the smaller alveoli to collapse and transfer their volume of air to larger neighboring alveoli, which become overdistended. In both cases, the effect on compliance is deleterious: FRC declines, the work of breathing increases, \dot{V}/\dot{Q} matching is compromised, and respiratory failure ensues. Surfactant not only reduces absolute surface tension, but it

also does so in a graded fashion. In small-radius alveoli, the phospholipid layer is condensed and its effect on surface tension is great. As the alveolus expands, the phospholipid molecules spread out and impart a gradually decreasing effect on surface tension. This differential efficiency of surfactant function allows alveoli of different sizes to coexist in a stable fashion.

Surfactant composition is an important determinant and predictor of fetal lung maturity. By the 20th week of gestation, collections of surfactant appear in type II cells within cytoplasmic granules called lamellar bodies. Thereafter, surfactant begins to appear in the developing terminal sacs. Infants born at 25 weeks occasionally survive without respiratory support; at 30 weeks' gestation, the risk of respiratory distress approaches 50%, and by 35 weeks' gestation, nearly all fetuses are capable of unassisted extrauterine respiration. There is considerable variability with respect to the timing of lung maturity, however, and clinical indices that assess lung maturity are useful in planning early delivery. The most common index of lung maturity is the amniotic fluid ratio of lecithin (phosphatidylcholine) to sphingomyelin, that is, the L/S ratio. Because amniotic phosphatidylcholine is derived solely from surfactant and sphingomyelin derives from all cell membranes, this provides a convenient self-indexed measurement of surfactant production that is independent of changes in amniotic fluid volume. An L/S ratio of 2.0 is achieved in the normal fetus by 35 weeks' gestation and is associated with an extremely low risk of RDS. Values of 1.5 to 2.0 are considered "immature" but of low risk. Values below 1.5 are associated with increased risk, and those below 1.0 are considered high risk. A more detailed test, the Lung Profile, utilizes the L/S ratio as well as percentages of phosphatidylglycerol and phosphatidylinositol to predict more accurately the risk of RDS. More recently developed tests of fetal lung maturity include the direct measurement of amniotic fluid surfactant concentration by fluorescence polarization and the quantitation of amniotic fluid lamellar bodies.

The fact that some infants born before 35 weeks' gestation do not manifest RDS led to the idea of stress-induced lung maturation. Fetal stress that promotes preterm labor also appears to promote accelerated lung maturation. This observation prompted the use of exogenous maternal corticosteroid administration to promote early lung maturation in fetuses expected to deliver early because of preterm labor or induced delivery. Exogenous corticosteroids appear to accelerate the maturation of surfactant phospholipids as well as increasing the synthesis of surfactant proteins.³⁵

Postnatal administration of exogenous surfactant has become a mainstay of treatment not only for prematurity-associated RDS but also for a wide variety of neonatal lung diseases associated with reduced compliance. Surfactant replacement therapy has been proved to decrease the incidence and severity of RDS, especially when used in conjunction with antenatal maternal corticosteroids, and it appears to be efficacious in both prophylactic and rescue strategies. Natural surfactant preparations derived from animal lungs contain SP-B and SP-C, and have demonstrated superiority over synthetic surfactants that do not contain these proteins. Synthetic surfactants (which are safer and less immunogenic) containing SP-B/C protein analogues are under development. These preparations are aerosolized into the airway through an endotracheal tube with positive-pressure ventilation. Although initially designed for treatment of RDS, they appear to reduce ventilatory requirements and complications in a variety of diseases characterized by reduced compliance, including congenital diaphragmatic hernia, meconium aspiration, persistent pulmonary hypertension of the newborn (PPHN), and ARDS in older patients.³⁶

Pulmonary Hypoplasia

Pulmonary hypoplasia refers to a condition in which pulmonary parenchymal tissue is abnormally reduced relative to

body size. It is defined pathologically by reduced lung dry weight or DNA content relative to body mass and reduced alveolar number per unit volume. Although pulmonary hypoplasia may occur rarely as a primary disease, it is usually a stereotypical consequence of mechanical compression during lung development. Clinically, secondary pulmonary hypoplasia is associated most commonly with congenital diaphragmatic hernia, giant omphaloceles, and oligohydramnios caused by fetal renal dysfunction or urinary obstruction. Whether the true cause of pulmonary hypoplasia is mechanical compression, some alteration in fetal lung fluid dynamics, or a combination of both has not yet been elucidated.

Whatever the cause, pulmonary hypoplasia results from arrested development of the tracheobronchial tree and pulmonary vasculature. Depending on the severity of compression, the sequential binary branching of the developing airway may be arrested well before the usual 22 or 23 divisions, resulting in fewer respiratory units and a reduced pulmonary capillary network. The pulmonary arterial tree is not just quantitatively diminished, but it is histologically and functionally abnormal as well. The pulmonary arterioles in affected lungs are characterized by thickening of the muscular media, abnormal extension of the muscular media into terminal arterioles, and hyperreactivity of the vascular smooth muscle cells to vasoconstrictive stimuli. Endothelin is a potent vasoconstrictor that also acts as a smooth muscle mitogen, and may have a role in the development of fetal pulmonary vascular hyperplasia.³⁷ The pathophysiologic effects of pulmonary hypoplasia, therefore, include both inadequate gas exchange and persistent pulmonary hypertension.

In most cases of pulmonary hypoplasia, the life-threatening consequences of hypoplasia are related to persistent pulmonary hypertension, not to inadequate gas exchange. Most patients with congenital diaphragmatic hernia, for instance, have one or more blood gas measurements that document the potential for adequate gas exchange. Subsequent physiologic deterioration and death result from progressive, refractory pulmonary hypertension; extrapulmonary right-to-left shunting; and global hypoxemia. These subjects are covered more thoroughly in the discussion of persistent fetal circulation.

Ventilatory Support

Ventilatory management of pediatric patients has become increasingly complex as technologic innovation has expanded the number of available options. These advances have been motivated by a need to improve gas distribution in diseased lungs, to avoid complications associated with barotrauma, and to provide better synchronized and tolerated ventilation. Although conventional positive-pressure ventilation remains the mainstay of management for most infants and children requiring ventilatory support, a number of nonconventional technologies have gained increasing acceptance in certain situations where conventional techniques have proved inadequate.

Conventional Mechanical Ventilation

Conventional positive-pressure ventilators deliver a bulk flow of oxygen-enriched gas to the lungs through an endotracheal tube. In general, they are classified according to the method used to initiate and terminate a single ventilatory cycle. Volume-cycled ventilators deliver a predetermined tidal volume of gas. Respiratory rate (cycles/min), flow rate (L/min), inspiratory-to-expiratory ratio, and inspired oxygen concentration are manipulated to achieve certain respiratory goals, but the actual termination of the positive-pressure breath occurs when the preset tidal volume has been delivered. Volume-cycled ventilation has the advantage of providing precise control of

minute ventilation regardless of lung compliance, and it is used routinely in adults and older children.

Infants and small children historically have not been managed with volume-cycled ventilators. Although control of minute ventilation is equally important in this group, the risks of barotrauma are high, particularly in neonates with pulmonary immaturity. A reduction in compliance will result in a reciprocal increase in pressure during volume-cycled ventilation, leading to overdistention of ventilated alveoli, \dot{V}/\dot{Q} mismatching, alveolar rupture and pneumothorax, and the chronic lung changes observed with barotrauma. For this reason, precise control of inspiratory pressure is preferable to volume control.

Most neonatal and pediatric ventilators are technically not pressure cycled, but instead are time cycled and pressure limited. Instead of ventilatory flow ceasing when a preset pressure is reached, flow continues at a plateau pressure until the inspiratory time is reached. This improves tidal volume consistency and distribution. Constant monitoring of respiratory function (e.g., continuous transcutaneous oximetry) is imperative to prevent hypoventilation in the event of a sudden decrease in compliance and tidal volume.

The usual options for ventilatory modes in pediatric ventilator management are essentially identical to those used in adults: control, assist control, intermittent mandatory ventilation (IMV), synchronized IMV, and pressure support. The function and utility of these modes in children are similar to their use in adults. Pressure support, in which each spontaneous breath is assisted by supplemental positive pressure, is becoming the preferred mode in many settings where the patient is conscious and breathing spontaneously. It is particularly effective in the weaning of mechanical ventilation and restoring respiratory muscle strength.

For most modes, parameters are selected that determine gas exchange: FiO_2 , respiratory rate, PIP, and PEEP. Inspiratory flow rates may need to be adjusted to provide an appropriate inspiratory/expiratory ratio within the constraints of the preset respiratory rate. PEEP is adjusted to optimize compliance and FRC; PIP is adjusted to provide an adequate tidal volume. Flow rates are adjusted to match the time constant requirements of particular disease processes. The FiO_2 is minimized to avoid pulmonary oxygen toxicity and retinopathy. The mean airway pressure (MAP), which is measured and represents the area under the time–pressure curve, is probably the single best parameter to follow for monitoring changes in the level of ventilatory support required as well as the risk of barotrauma.

Complications of Mechanical Ventilation in Infants and Children. Conventional breathing and mechanical ventilation both involve the bulk transport of air through conducting airways to gas-exchange chambers (alveoli), where diffusion occurs across the alveolar–capillary membrane. In many disease states associated with reduced lung compliance, the high pressures necessary to produce this bulk flow of gas during mechanical ventilation result in considerable iatrogenic lung injury. Ventilator-associated lung injury (VALI) is manifested both by parenchymal changes and edema, which further reduce compliance and diffusion, and mechanical disruption of small bronchi and alveoli resulting in pulmonary interstitial emphysema (PIE), mediastinal emphysema, and pneumothorax. Excessively high inspiratory pressures also impair venous return to the right atrium, thereby reducing preload, lung perfusion, gas exchange, and global cardiac output.

Whether VALI is caused by pressure itself or by physical overdistention of the more compliant alveoli is a subject of considerable debate. Current evidence seems to favor the structural overdistention of alveoli as the principal cause of iatrogenic lung injury, leading some to prefer the term *volutrauma* to the more accepted term *barotrauma*.^{38–40} Volutrauma consists of two distinct entities: alveolar overdistention and cyclical atelectasis, in which the repetitive collapse of some alveoli creates

shear forces that damage the walls of adjacent alveoli. The consequences of alveolar overdistention include disrupted endothelial and epithelial barrier function, increased permeability, interstitial edema, protein deposition, and fibrosis.

Although alveolar volume and overdistention may be the most important cause of VALI, the use of high ventilatory pressures in volutrauma-injured lungs increases the risk of interstitial emphysema and pneumothorax. Since small changes in alveolar volume are difficult to accurately measure in the ventilated patient, inspiratory pressures are still more commonly used to monitor and predict lung injury. Peak inspiratory pressures in settings of low compliance and high respiratory rate are often exaggerated, and inspiratory plateau pressures are now thought to correlate better with the eventual development of VALI.

Innovations in Pediatric Conventional Ventilation.

Numerous developments in ventilation management have occurred in recent years that aim to make ventilation more effective, more physiologic, and less damaging.^{41–43} Trends in both neonatal and pediatric respiratory support have favored the widespread adoption of less invasive and more natural techniques. The simplest of these techniques is the application of CPAP by mask—essentially, the application of PEEP in a nonintubated patient. Like PEEP, CPAP recruits and maintains FRC and improves \dot{V}/\dot{Q} matching and compliance. A more recent development is bilevel CPAP, or BiPAP, in which positive airway pressure is incrementally increased during the inspiratory phase, more precisely reproducing the advantages of PEEP. These noninvasive ventilatory support techniques have been useful in reducing the need for, and duration of, invasive mechanical ventilation in infants and children with respiratory compromise.

In patients requiring mechanical ventilation where high pressures would traditionally have been employed, newer strategies using small tidal volumes have been devised to reduce VALI. In “open lung ventilation,” higher-than-usual levels of PEEP are applied to recruit and maintain alveoli against cyclic atelectasis, and very small tidal volumes are delivered in volume-control mode to avoid alveolar overdistention. In this strategy, the use of “permissive hypercapnia” allows for a reduced minute ventilation that keeps ventilator rates acceptably low.

With advances in ventilator technology, volume-controlled ventilation has again become safe for use in neonatal and pediatric patients, and may have some distinct advantages over pressure-limited ventilation in certain circumstances. In “volume guarantee” mode, ventilators provide pressure-regulated volume control (PRVC) ventilation in which tidal and minute volumes are preset, and which the ventilator delivers in a pressure-limited fashion. The ventilator calculates compliance changes continuously and adjusts flow rates to minimize inspiratory pressure with each breath. The resulting ventilation mode is a hybrid of volume- and pressure-regulated techniques and may be helpful in infants with bronchopulmonary dysplasia and rapidly changing compliance who are at risk for alveolar injury.⁴⁴

Although not currently employed in neonatal ventilation, airway pressure release ventilation (APRV) is gaining attention in pediatric ventilatory management. In APRV, continuous positive pressure is maintained at a high level during spontaneous ventilation by the use of a CPAP valve. These longer periods of high CPAP are punctuated by rapid, brief drops in airway pressure that are controlled by a “release” valve. During airway decompression, the lungs deflate and CO_2 is expelled. During rapid inflation, the lungs expand again and FRC is preserved. APRV has the advantage of allowing spontaneous ventilation to be superimposed on a high-PEEP/high-compliance system with decreased work of breathing while avoiding overinflation due to breath-stacking. Studies in adults have not demonstrated a survival advantage over conventional ventilation, but other parameters such as total time on ventilatory support and incidence of VALI may be decreased.⁴⁵

Currently, the area of most rapid change in ventilatory management in infants and children relates to the synchronization

of patient-initiated respiratory efforts and ventilator-delivered respiratory support. While pressure support ventilation (PSV) represented a significant advance in patient participation during ventilatory support, patients on PSV still experienced significant complications related to asynchrony with the ventilator. The inaccurate matching of respiratory triggering and demand with ventilator support results in several major problems for the ventilated patient. Breath-stacking, or auto-PEEP, occurs when asynchrony results in the accumulation of inspired volumes before complete exhalation, resulting in excessive FRC and alveolar overdistention. At high levels this causes VALI, but even at modest levels this results in the creation of steady-state lung volumes associated with reduced compliance, impaired gas flow, and diminished venous return. Another important consequence of ventilatory asynchrony is patient discomfort and anxiety, which leads to the overuse of sedative medications that suppress spontaneous ventilation.

Two novel ventilator technologies that address this important limitation in conventional ventilation are proportional assist ventilation (PAV) and neurally adjusted ventilatory assist (NAVA).^{46,47} In PAV, fine adjustments in ventilator pressures and flows are continuously made based on calculated parameters, resulting in a more precise and variable delivery of breath-to-breath ventilator support targeted to predicted patient demand. In practice, the reliance on complicated formulas using difficult-to-measure physiologic parameters has limited the usefulness of PAV in pediatric settings. The recent development of NAVA has eliminated many of the shortcomings of PAV while still maintaining many of its touted advantages. In NAVA, intrinsic diaphragm activity is monitored by an array of bipolar electrodes in the distal esophagus that measure diaphragmatic action potentials, or electrical activity of the diaphragm (EADi). The timing and strength of EADi potentials correspond precisely with the initiation of a central nervous system trigger event and with the predicted demand for tidal volume. This allows ventilatory assistance to be matched and timed much more closely to patient activity, improving comfort and reducing inspiratory pressures and auto-PEEP.^{48,49}

Unconventional Mechanical Ventilation. Several novel ventilatory techniques have emerged recently that attempt to mitigate barotrauma and hemodynamic compromise by providing effective ventilation without excessive pressures. These techniques employ extremely high ventilatory rates and tidal volumes less than or equal to anatomic dead space. Although numerous variations exist, the most popular modes are high-frequency jet ventilation (HFJV) and high-frequency oscillatory ventilation (HFOV). In HFJV, a small cannula is advanced through the endotracheal tube and used to deliver rapid, low-volume bursts of inspired gas. Ventilation does not require bulk flow, but it relies on several poorly defined physical processes, the most important of which is probably coaxial flow. In coaxial flow, the jet stream induces continuous rotational flow of inspired gas down the center of the airway and reverse rotational flow of expired gas along the perimeter of the airway (Fig. 103.6). In HFOV, ventilation is driven by the oscillations of a diaphragm within a closed noncompliant system. The cyclical compression and expansion of gas within the system generate high-velocity, streaming flow patterns that are similar to the coaxial flow seen in HFJV. The major difference between the two is that the expiratory phase is active in HFOV, as opposed to the passive expiration seen in both HFJV and conventional ventilation. This difference may make HFOV more effective in reducing air leaks from bronchopleural fistulas and less likely to cause air trapping and overdistention in lungs with longer and more heterogeneous time constants.

Unconventional ventilator management is often unpredictable and counterintuitive. For instance, in HFOV the FiO_2 , MAP, frequency (cycles per second, or Hz), and amplitude (volume displacement caused by oscillation of the diaphragm) are preset. The amplitude is not an accurate reflection of the

FIGURE 103.6. Proposed coaxial flow pattern during high-frequency jet and oscillatory ventilation. Gas inflow is confined to the center of the airway lumen, and outflow is confined to the periphery. (Adapted from Harris TR, Wood BR. In: Goldsmith JP, Karotkin EH, eds. *Assisted Ventilation of the Neonate*, 3rd ed. Philadelphia, PA: WB Saunders; 1996.)

tiny tidal volume produced at the end of the endotracheal tube and is therefore useful as a relative, “unitless” measurement only. In practice, the adequacy of the amplitude can be judged subjectively by observing chest-wall vibration. Increasing PaO_2 usually requires increasing the FiO_2 or the MAP, which recruits alveoli and increases FRC similar to the use of PEEP. In some conditions, the MAP required actually may be higher than that required in conventional ventilation, but the PIP is far less. Reducing PaCO_2 actually may require reducing the oscillatory rate to allow more time for gas displacement and more effective gas streaming.

In general, high-frequency ventilatory techniques are effective at promoting improved CO_2 elimination at lower pressures than conventional ventilation. Improved oxygenation is less reliable. HFJV and HFOV are both helpful in providing respiratory support in infants with preexisting barotrauma and air leaks. The ability of HFOV to actively promote enhanced CO_2 removal and generate a respiratory alkalosis at lower pressures has made it useful in managing infants with persistent pulmonary hypertension, particularly those with congenital diaphragmatic hernia.

HFOV has largely supplanted jet ventilation as the preferred modality in unconventional ventilation, and has been widely adopted by neonatologists as the most reliable and efficacious form of advanced ventilatory support. Despite this widespread clinical endorsement, a metastudy of recent reports

of the safety and efficacy of HFOV in neonates with respiratory distress secondary to prematurity did not show any benefit for HFOV over conventional ventilation. The role of HFOV in neonates with other causes of respiratory failure (congenital diaphragmatic hernia, developmental lung anomalies, bronchopleural fistula) has not been delineated.

Liquid ventilation is a novel, experimental approach to respiratory support that currently is undergoing clinical trials in a variety of settings. In this approach, a liquid perfluorocarbon solution is instilled into the lungs instead of a gas mixture. Because many forms of respiratory failure are associated with surfactant insufficiency and reduced compliance, the substitution of liquid for gas in the alveolus eliminates the liquid–gas interface, reduces surface tension, and improves compliance. The improvement of mechanical properties in the perfluorocarbon-filled lung allows ventilation to occur at lower pressures and less barotrauma. The solubility of oxygen and carbon dioxide in perfluorocarbon solutions is extremely high, allowing respiratory gases to diffuse easily across the alveolar–capillary membrane.

Although total liquid ventilation requires a closed circuit and is clinically impractical, a partial liquid ventilation technique has been developed that is logistically feasible and promises to provide ventilatory benefits to some patients with reduced lung compliance.⁵⁰ In partial liquid ventilation, perfluorocarbon is instilled at a volume equal to FRC, and conventional ventilation then is superimposed on the liquid-phase FRC. In essence, this is analogous to providing “liquid PEEP,” and improves pulmonary mechanics with little increase in alveolar distending pressure. The optimal role for partial or total liquid ventilation remains a subject for further investigation.

Extracorporeal Support

In certain situations, both conventional and unconventional ventilatory techniques are inadequate to provide gas exchange in the face of overwhelming pulmonary dysfunction. Under these circumstances, the use of extracorporeal membrane oxygenation (ECMO) may succeed in sustaining oxygen delivery and carbon dioxide removal until the underlying cause of respiratory failure is reversed and physiologic improvement occurs. It is important to recognize that, like conventional ventilation, ECMO is a supportive rather than therapeutic technique and has a limited window of utility imposed by the adverse effects of the technology itself.

Several variations of ECMO technology exist, but all share the same underlying principles: the partial diversion of blood from the patient to an external oxygenator (membrane or hollow fiber), the ex vivo exchange of oxygen and carbon dioxide, and return of blood to the circulatory system. The circuit is driven by either a roller or centrifugal pump similar to that used for routine cardiopulmonary bypass. Systemic anticoagulation is necessary to prevent thrombosis from occurring in the extracorporeal circuit.

Two basic methods of providing ECMO support are currently available: venoarterial (VA) and venovenous (VV). In VA ECMO, the right common carotid artery (RCCA) and jugular vein are cannulated in infants. In adolescents and young adults, the femoral artery is preferred. Venous inflow to the system results from passive drainage of the right atrium; arterial flow back to the patient occurs in the aortic arch (Fig. 103.7). As return flow is into the aorta, partial cardiac bypass occurs, which may provide significant benefit when respiratory failure is accompanied by compromised cardiac performance. The pump flow rate is advanced to 100 to 120 mL/kg per minute, which approximates 60% to 80% of cardiac output. Although VA ECMO directly augments cardiac output, the return of oxygenated blood to the descending aorta and the flow of desaturated blood through the pulmonary circuit and left heart results in both pulmonary vasoconstriction and reduced delivery of oxygen to the coronary arteries.

FIGURE 103.7. Components of a standard venoarterial extracorporeal membrane oxygenation (ECMO) circuit. (Adapted from O'Rourke PP. In: Holbrook PR, ed. *Textbook of Pediatric Critical Care*. Philadelphia, PA: WB Saunders; 1993.)

The consequences of RCCA cannulation in infants are undefined, and the long-term effects of carotid occlusion are the subject of increasing clinical investigation.^{51–53} Although infants subjected to ECMO have a slightly increased incidence of neurologic injury, radiologic evidence for cerebral hypoxia does not seem to be lateralized to the right side. Carotid artery reconstruction (as opposed to ligation) at the time of decannulation has been studied extensively, with conflicting reports of long-term patency. Even (or especially) when patency is established, the theoretical risks of platelet embolism or plaque disruption later in life at a stenotic anastomosis are undefined. Longer-term neurodevelopmental studies are necessary to assess the potential benefits of this practice.

In VV ECMO, the circuit is interposed into the venous side of the circulation, with blood returning to the right atrium. This mode of extracorporeal support is less efficient than VA ECMO, resulting in a lower maximal SaO_2 because of the phenomenon of recirculation. Because both cannulas are positioned on the venous side, some of the oxygenated perfusate will be siphoned back into the venous return instead of flowing forward to perfuse end organs. The degree of recirculation is monitored by comparing oxygen saturations of the venous drainage and the arterial blood: the venous drainage saturation should be less than the arterial saturation. Although it provides no direct support of cardiac output, this method obviates the ligation and sacrifice of a carotid artery, avoids some of the risk of arterial embolization, and provides well-oxygenated blood for pulmonary and coronary circulation. Even in patients with decreased cardiac contractility, the improvement in oxygen delivery to the myocardium afforded by VV ECMO results in significant enhancement of cardiac output and may obviate VA ECMO. For most infants and

children with adequate cardiac function, VV ECMO may become the modality of choice for extracorporeal support.⁵⁴

Indications for ECMO vary among institutions. Because of the high cost and potential for complications, ECMO is justifiable only when all other available therapies for respiratory failure have proved inadequate and when quantifiable parameters predict a mortality rate of 80% or greater with conventional management. Several methods of providing a quantitative estimate of respiratory failure have been used to predict mortality with conventional ventilation and guide the use of ECMO. Perhaps the most widely used index is the oxygenation index (OI), which compares ventilatory support parameters (MAP and FiO_2) with gas-exchange results (postductal PaO_2):

$$\text{OI} = (\text{MAP})(\text{FiO}_2)/\text{PaO}_2 \times 100$$

An OI greater than 40 predicts a mortality rate of 80% and is a commonly cited threshold indicator for the use of ECMO. Another useful, although more burdensome, parameter for quantifying respiratory failure and predicting mortality is the alveolar-arterial oxygen gradient ($\text{PAO}_2 - \text{PaO}_2$), which when greater than 600 predicts a mortality rate of 80%. Other inclusion criteria for ECMO include the absence of a major intrinsic cardiac defect, chromosomal abnormality, or significant intraventricular hemorrhage; a gestational age greater than 33 weeks; weight greater than 2 kg; and an underlying respiratory pathology that is judged to be reversible.

The use of exogenous surfactant, oscillatory ventilation, and inhaled nitric oxide has had two major effects on ECMO utilization: many infants have avoided ECMO support altogether, while others have become candidates for less-invasive VV support. Consequently, the reduced number of patients requiring VA ECMO support is a more varied, complicated, and physiologically challenged group.^{55,56} Results for extracorporeal support are age and diagnosis dependent. Infants with respiratory failure (meconium aspiration syndrome, RDS, sepsis) appear to benefit most from extracorporeal support. This is most likely because neonatal respiratory failure often is associated with reversible pulmonary hypertension, and ECMO allows for the normalization of PO_2 , PCO_2 , pH, and pulmonary vascular resistance without the aggressive ventilatory support that frequently causes iatrogenic lung injury and chronic lung disease. Neonates with reversible, idiopathic PPHN benefit from ECMO for the same reasons.

Neonates with respiratory failure and pulmonary hypertension attributable to congenital diaphragmatic hernia and pulmonary hypoplasia appear to benefit from ECMO, but the improvement in survival over conventional management is not as significant. This may reflect the irreversible problems related to inadequacy of alveolar number and microvascular development associated with pulmonary hypoplasia. The results of ECMO in children and adolescents with respiratory failure resulting from ARDS, trauma, bronchopleural fistula, viral pneumonia, or aspiration are less convincing, and the role of ECMO in these diseases is not yet well defined.⁵⁷

CARDIOVASCULAR PHYSIOLOGY AND SUPPORT

Fetal Circulation

Fetal circulation has evolved to utilize an external organ of gas exchange, the placenta, while maintaining the anatomic relationships that will later be necessary in extrauterine life when responsibility for gas exchange transitions abruptly to the lungs. The fetal circulatory system is characterized by asymmetric ventricles that function in parallel, an arrangement made possible by two anatomic shunts—the *foramen ovale* and *ductus arteriosus*. These shunts make possible the nonrandom

FIGURE 103.8. Fetal circulation. (Adapted from Bloom RS. In: Farnoff AA, Martin RJ, eds. *Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant*, 6th ed. St. Louis, MO: Mosby; 1997.)

distribution of blood of varying oxygen contents and the delivery of adequate amounts of oxygen and substrate to developing organs (Fig. 103.8).

Well-oxygenated blood returning from the placenta and umbilical cord passes through the hepatic *ductus venosus*, into the inferior vena cava (IVC) and immediately into the right atrium. Ductus venosus blood mixes little with the less oxygenated blood in the infrahepatic IVC and flows relatively undisturbed (in a laminar fashion referred to as streaming) along the medial wall of the IVC, through the right atrium, across the foramen ovale, and into the left atrium. This oxygen-rich blood then is pumped by the left ventricle into the aortic arch, where it is distributed to the developing heart, brain, and upper body (Fig. 103.9). The less oxygenated blood in the IVC and superior vena cava (SVC) flows preferentially through the right atrium to the right ventricle and is pumped into the pulmonary artery, where most of it is shunted through the ductus arteriosus into the descending aorta. A small amount of pulmonary artery flow provides substrate to the lungs. Descending aortic flow is distributed to the developing organs of the lower body, with most of the flow being diverted back to the placenta through the two umbilical arteries. Flow through the placental circulation approximates 40% of cardiac output.

The fetal pattern of blood flow is made possible by high pulmonary vascular resistance, which directs the flow of oxygen-

FIGURE 103.9. Oxyhemoglobin saturations in the fetal circulation. Preferential flow of saturated blood from the inferior vena cava (IVC) into the left atrium (LA) and desaturated blood from the superior vena cava (SVC) into the right atrium (RA) results in the distribution of blood with higher oxygen content to the aortic arch (Ao) and developing brain. (Adapted from Rudolph AM. *Changes in the circulation after birth*. In: Rudolph AM, ed. *Congenital Diseases of the Heart*. Chicago, IL: Year Book Medical; 1974.)

poor blood from the pulmonary artery into the descending aorta. Only 5% to 10% of pulmonary artery flow actually traverses the pulmonary capillary bed. This minimizes the return of less-oxygenated blood through the pulmonary veins and prevents mixing with the oxygen-rich blood in the left ventricle destined for the heart and brain. The relatively low afterload presented to the right ventricle by the low-resistance shunt across the ductus arteriosus accounts for the fact that fetal right ventricular output exceeds left ventricular output, in some estimates by 40% to 100%.^{58,59} Mechanisms of increased pulmonary resistance in the fetus include mechanical compression of pulmonary vessels in the fluid-filled lung and vasoconstriction secondary to hypoxemia, leukotrienes, and the peptide mediator endothelin-1.⁶⁰

Transitional Circulation

- 10 At birth, profound changes in circulatory patterns, hemodynamics, and gas exchange occur as a result of the abrupt withdrawal of placental support. Transitional physiology is characterized by the cessation of placental blood flow and gas exchange and the simultaneous increase in blood flow and gas exchange in the lungs. As amniotic fluid is expelled from the lungs by compression during birth and the lungs expand with the infant's first breath, alveolar expansion causes an immediate reduction in pulmonary vascular resistance secondary to increased traction on larger parenchymal vessels and decreased intra-alveolar pressure transmitted to alveolar microvessels.

These purely mechanical changes account for a fourfold reduction in pulmonary vascular resistance (PVR), contributing significantly to the 15-fold overall reduction in PVR that occurs at birth. Pulmonary artery pressures fall more slowly over the first weeks of life and may approximate systemic pressures for the first several days of life.

Increased local oxygen concentrations reduce hypoxic pulmonary vasoconstriction through mechanisms mediated by endothelial-derived intermediates, such as nitric oxide (NO) and prostacyclin.^{61,62} The enzymes responsible for the production of NO and prostacyclin in the pulmonary circulation, NO synthase and cyclooxygenase, undergo developmental maturation late in gestation, and their activity increases rapidly in response to birth-related stimuli, ventilation, and oxygenation. NO and prostacyclin act on pulmonary vascular smooth muscle cells to increase intracellular concentrations of cyclic guanosine monophosphate (GMP) and cyclic adenosine monophosphate (cAMP), respectively, which results in relaxation and vasodilation. ATP, released directly from oxygenated red blood cells in the pulmonary circulation, is also a potent mediator of vasodilation. These vasodilatory mediators are countered by vasoconstrictor substances such as endothelin, thromboxane, and cytochrome P450 pathway products.

The sudden decrease in pulmonary vascular resistance causes a dramatic increase in pulmonary blood flow and left atrial return. Left ventricular preload increases, resulting in increased left ventricular stroke volume and output. Right atrial return is reduced as placental flow ceases. Elevated left atrial pressure and reduced right atrial pressure cause closure of the flaplike foramen ovale, eliminating one of the fetal extrapulmonary shunts.

The other shunt, the ductus arteriosus, begins to close by vasoconstriction immediately. This process is mediated by both a withdrawal of placental-derived prostaglandins and an increase in oxygen tension, a potent vasoconstrictive stimulus for ductal tissue. Physiologic duct closure usually occurs by 24 hours but may take up to 3 days. Anatomic duct obliteration resulting from thrombosis and fibrosis may take several weeks or months. When spontaneous closure of the ductus arteriosus does not occur, as often happens in the premature infant whose immature ductal tissue is unresponsive to vasoconstrictive mediators, significant physiologic problems may occur. If pulmonary artery pressures remain abnormally high, an anatomic right-to-left shunt may occur that diverts desaturated blood around the pulmonary system, drastically lowering systemic oxygen delivery. If pulmonary artery pressure falls normally, a left-to-right shunt will occur, increasing pulmonary blood flow above cardiac output. Pulmonary overcirculation causes pulmonary edema and congestive heart failure in the short term and irreversible pulmonary hypertension in

the long term, if uncorrected. Indomethacin administration, which inhibits prostaglandin synthetase, is effective in promoting ductal closure in most premature infants if given within the first 2 weeks of life. Failure of medical therapy indicates the need for surgical duct ligation.

Another event in the transition to extrauterine circulation involves vasoconstrictive or mechanical occlusion of the cord vessels. The abolishment of this “shunt” increases left ventricular afterload and systemic blood pressure and, along with increased left ventricular preload, accounts for an immediate increase in blood flow to target organs. Ductus venosus closure occurs by stasis and thrombosis as return flow through the umbilical vein ceases.

Postnatal Circulation and Cardiac Performance

Following the transition from fetal to neonatal life, the circulatory system is characterized by two separate cardiovascular circuits operating in a “series” configuration. By definition, right and left heart cardiac outputs are identical and can be considered symmetric despite discrepancies in system pressures and contractile properties. The series configuration has great significance in that it imposes a degree of interdependence on the two circuits that does not exist in utero. Pathologic changes in one circuit necessarily impact the other circuit by virtue of alterations in the other circuit’s preload or afterload. Failure of complete separation of the two circuits results in the deleterious shunting of blood from the pulmonary to systemic circuit or vice versa.

Cardiac output is determined by the same parameters in the neonate as in the adult: heart rate and stroke volume. Stroke volume, in turn, is dependent on three factors: preload, contractility, and afterload. Although a detailed discussion of these four determinants of cardiac performance is beyond the scope of this chapter, it is instructive to consider some of the differences between pediatric and adult cardiac function relative to these four variables. These differences account for the fact that, in general, neonatal and pediatric patients have less cardiovascular reserve than do adolescents and young adults.

Heart rate, an important determinant of cardiac output in infants, becomes less important in childhood and adolescence. In fact, neonates are commonly referred to as rate dependent. The normal range for heart rate in neonates is higher than that in adults and decreases gradually throughout childhood to adult levels (Table 103.6). In adults, changes in heart rate result in little change in cardiac output because of compensatory

TABLE 103.6

NORMAL RANGE OF VITAL SIGNS

■ AGE	■ HEART RATE (BEATS/MIN)	■ SYSTOLIC BLOOD PRESSURE (mm Hg)	■ DIASTOLIC BLOOD PRESSURE (mm Hg)	■ RESPIRATORY RATE (BREATHS/MIN)
Premature infant				
1 kg	120–140	36–58	18–38	40
3 kg	120–140	50–72	26–46	40
Term infant	120	65–80	30–50	40
0–12 mo ^a	100–120	105	65	40

changes in other parameters. When heart rate decreases, ventricular filling and stroke volume increase, and cardiac output is minimally altered. Reciprocal changes occur when heart rate increases. In neonates and, to a lesser extent, in children, these compensatory changes are less effective and changes in heart rate produce corresponding changes in cardiac output. The explanation for this observation lies in the fact that increased ventricular filling times and pressures fail to generate increased end-diastolic and stroke volumes because of decreased myocardial compliance and a blunted Frank-Starling mechanism, as discussed later.

The sympathetic innervation of the heart is relatively underdeveloped in the neonate, resulting in an autonomic imbalance with respect to cardiac function. Neonates respond to physiologic challenges in a predominantly vagal, or parasympathetic, fashion. Sinus bradycardia is therefore a common stereotypical response in the critically ill neonate to many stimuli, including hypoxemia, acidosis, hypoglycemia, intracranial hypertension, abdominal distention, and pulmonary aspiration. Because bradycardia is also more likely to result in an uncompensated decrease in cardiac output, prompt recognition and treatment of bradycardia are more urgent in these patients.

Preload refers to the myocardial fiber stretch at end diastole. Fiber stretch is related to end-diastolic volume, which in turn is related to end-diastolic pressure. The Frank-Starling mechanism describes this relationship: an increase in end-diastolic volume and fiber length produces an increase in stroke volume (Fig. 103.10). This phenomenon most likely is explained by changes in contractile fiber geometry that result from increased stretch. The Frank-Starling mechanism is not synonymous with an increase in contractility, which would produce an increased stroke volume at the same preload. This mechanism is less effective in neonates than in adults in producing an increase in myocardial performance. The immature heart is less compliant than the adult heart, so increases in end-diastolic pressure therefore do not produce similar increases in end-diastolic volume and fiber length. Furthermore, neonatal and infant hearts operate at a higher baseline end-diastolic volume (nearer the maximal fiber length) under normal circumstances, leaving less reserve for further effective increases in preload. These observations explain why the neonatal cardiovascular response to preload enhancement is less pronounced than in adults and why the neonate is generally more susceptible to congestive failure when challenged with a volume load.

Contractility refers to the magnitude and velocity of tension development by the cardiac myocytes in response to contractile

stimuli. The contractile, or inotropic, state of the heart is influenced by many factors, including the availability of oxygen, calcium, and catecholamines. An increase in contractility does not result in a shift upward along the Frank-Starling curve, but rather it results in a shift of the entire curve to reflect a greater stroke volume generated at every preload. The neonatal heart is immature in several respects compared with the adult heart. Most importantly, the neonatal heart has a lower concentration of contractile fibers, generating less tension during contraction.⁶³ This is reflected in the lower mean arterial pressures observed throughout childhood. About 60% of the adult cardiac myocyte mass consists of contractile myofibrils, compared with 30% in fetal myocytes. Additional causes of reduced contractility include an underdeveloped sarcoplasmic reticulum and T-tubule system for releasing calcium, a lower concentration of myocyte cell surface β -adrenergic receptors, and decreased sympathetic innervation.⁶⁴ The structural and functional immaturity of the infant heart account for the relatively greater sensitivity to negative inotropic stimuli, the greater requirement for calcium to maintain the inotropic state, and the requirement for higher concentrations of inotropic agents to achieve measurable hemodynamic effects. In contrast, the neonatal heart is more resistant to the negative inotropic effects of hypoxemia and acidosis than the adult heart, possibly conferring some advantage with respect to the success of cardiopulmonary resuscitation.⁶⁵

Afterload refers to the resistance (or impedance) to ventricular output and is directly related to mean arterial pressure. During the transitional phase of circulation, afterload drops abruptly in the right ventricle as pulmonary vascular resistance drops. Left ventricular afterload increases immediately as the placental shunt is abolished but then falls as its output distributes to both the upper and lower body and a larger vascular bed. After the transitional phase, left ventricular afterload slowly increases throughout infancy and childhood, stimulating asymmetric growth of the left ventricle compared with that of the right. This growth is caused primarily by hyperplasia until 2 to 3 months of age, when hypertrophy becomes more important. Before adaptive left ventricular growth occurs, the neonatal heart is exquisitely sensitive and decompensates rapidly when exposed to increases in afterload, such as those that occur in aortic stenosis and aortic coarctation.

Oxygen Content and Delivery

Oxygen delivery is the product of cardiac output and oxygen content. Arterial oxygen content (CaO_2) is determined by the same set of variables in children as in adults:

$$\text{CaO}_2 = (\text{Hb})(1.34 \text{ mL O}_2/\text{g Hb})(\% \text{Hb saturation}) + \text{Dissolved O}_2$$

where Hb = hemoglobin.

Under most circumstances, dissolved oxygen is negligible. The main difference in the oxygen-carrying capacity of blood between neonates and older patients is the presence of fetal hemoglobin (HbF). The fetal red blood cell contains primarily HbF, a hemoglobin isomer with a higher affinity for oxygen than hemoglobin A (HbA), which predominates in adults. This gives HbF a lower P_{50} (the partial pressure of oxygen at which hemoglobin saturation is 50%), which is reflected in a leftward shift of the oxyhemoglobin dissociation curve relative to HbA (Fig. 103.11). This difference in affinities promotes the transfer of oxygen from maternal to fetal hemoglobin in the placenta. Following birth, neonatal red blood cells gradually accumulate HbA at the expense of HgF, which disappears by 4 months of age.

The presence of HbF in the neonate has several clinical consequences. Adequate hemoglobin saturation may occur at lower PaO_2 levels, but the benefits of this in the ex utero environment are deceiving. Greater oxygen affinity makes the unloading

FIGURE 103.10. Conceptual differences in cardiac performance between neonates and adults. The neonatal heart displays reduced contractility, a reduced response to augmented preload, and less reserve compared with the adult heart.

FIGURE 103.11. Representative oxyhemoglobin (HbO₂) saturation curves for newborn, infant, and adult. (Adapted from Hodson WA, Truog WE. In: Avery GB, Fletcher MA, MacDonald MG, eds. *Neonatology: Pathophysiology and Management of the Newborn*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

of oxygen in peripheral tissues more difficult. Increasing oxygen extraction during periods when oxygen demand temporarily exceeds supply is therefore less efficient. Increased difficulty in extracting oxygen from hemoglobin in peripheral tissues makes the neonate less tolerant than the older child of decreased oxygen delivery resulting from reduced hemoglobin concentration, hemoglobin saturation, or cardiac output. Constant attention to adequate oxygen content and cardiac output is therefore of paramount importance in the stressed neonate.

Pulmonary Hypertension and Persistent Fetal Circulation

In the older infant and child, PVR is normally low, which allows right ventricular output to equal that of the left ventricle at considerably lower pressure and contractile work. The instability of PVR in the neonate during the transitional period, along with the presence of anatomic connections between the pulmonary and systemic circuits, accounts for severe derangements in respiratory and hemodynamic performance in a wide variety of clinical disorders. These include acquired conditions (e.g., sepsis and meconium aspiration syndrome), congenital conditions (e.g., pulmonary hypoplasia associated with congenital diaphragmatic hernia [CDH]), idiopathic abnormalities in pulmonary vascular function (e.g., PPHN), and chronic microangiopathy, alveolar-capillary dysplasia, and fibrosis (“fixed” pulmonary hypertension secondary to uncorrected anatomic left-to-right shunting and pulmonary overcirculation).

The common denominator in these conditions is an abnormally high PVR, related both to vascular tone and to vascular anatomy. Pulmonary vascular tone is governed by the balance between molecular factors produced by vascular endothelium, including endothelin-1, nitric oxide, and prostacyclin. Endothelin-1 stimulates vascular smooth muscle contraction and proliferation, while both nitric oxide and prostacyclin cause vascular smooth muscle relaxation and inhibit proliferation. These mediators are important in prenatal, transitional, and postnatal regulation of pulmonary blood flow.

It is useful to categorize the etiologies of elevated PVR as related to vascular underdevelopment, maldevelopment, and

maladaptation. Pulmonary vascular underdevelopment occurs in pulmonary hypoplasia when the normal number of airway and vascular branchings is abbreviated due to extrinsic compression during lung development (e.g., CDH, congenital cystic adenomatoid malformation [CCAM]) and causes a reduced total capillary cross-sectional area. This condition may be moderated over time with compensatory alveolar and capillary growth, but it represents a fixed limitation to pulmonary blood flow during the initial postnatal period. Pulmonary hypoplasia also results in vascular maldevelopment characterized by medial smooth muscle hypertrophy and hyperplasia, resulting in exaggerated responses to vasoconstrictive stimuli. Maladaptation refers to the deleterious responses of a normal pulmonary vascular bed to pathologic stimuli, as occurs in bacteremia (e.g., β -streptococcal sepsis).

Not uncommonly, increased PVR results from a combination of these factors. For example, pulmonary hypoplasia not only causes a decreased cross-sectional area but also results in hyper-reactive arterioles prone to vasospasm. In “fixed” pulmonary hypertension, both fibrosis and decreased vessel numbers have been demonstrated. In perinatal aspiration of meconium or blood, ventilation is delayed and pulmonary hypertension ensues. Fetal exposure to maternally ingested nonsteroidal anti-inflammatory drugs causes spasm of the ductus arteriosus, increased fetal pulmonary flows and pressures, diminished NO synthase activity, and harmful pulmonary vascular remodeling.

Whatever the cause, increased PVR has several deleterious consequences. Increased right ventricular afterload results in decreased output, diminished pulmonary perfusion, and reduced left ventricular preload. Hypoxemia, hypercarbia, and globally decreased cardiac output result, which in turn cause metabolic acidosis. Increased PVR also promotes anatomic right-to-left shunting at the levels of the patent ductus arteriosus (PDA) and foramen ovale, a phenomenon referred to as persistent fetal circulation (PFC). This profoundly exacerbates the hypoxemia, hypercarbia, and acidosis already present. Because hypoxemia, hypercarbia, and acidosis are all potent mediators of pulmonary vasoconstriction, PVR is further increased. For this reason, pulmonary hypertension and PFC in the neonate frequently deteriorate into a vicious cycle that culminates in circulatory and metabolic collapse.

Therapy for pulmonary hypertension and PFC is directed at treating the underlying cause, removing the physiologic stimuli for pulmonary vasoconstriction, and introducing pharmacologic mediators of pulmonary vasodilatation. Analgesia, sedation, and neuromuscular blockade are commonly used to decrease endogenous stimulation of pulmonary vasoconstriction by catecholamines. The historical mainstays of management included aggressive ventilatory support to maximize PaO₂ and minimize PaCO₂, and systemic alkalization (pH 7.50 to 7.60) with sodium bicarbonate or tris-hydroxymethylaminomethane (THAM) if an adequate respiratory alkalosis could not be induced. Because aggressive ventilatory strategies result in lung injury, current management targets a normal pH and PaCO₂ while maintaining adequate oxygenation, often with HFOV. Pharmacologic agents with the ability to promote direct pulmonary vasodilatation would obviously be desirable.

Selective pulmonary vasodilation is presently unrealistic from a clinical standpoint. No pharmacologic substance has yet been identified that has vasodilatory effects specifically limited to the pulmonary circulation. Intravenous administration of nitroprusside, nitroglycerine, and PGE₁ all produce systemic vasodilatation as well, negating the reduction of resistance and pressure in the pulmonary circuit, and resulting in an unaltered right-to-left shunt. Tolazoline hydrochloride was commonly used in the past as a pulmonary vasodilator in neonates with pulmonary hypertension. Its vasodilatory effects can be ascribed both to α -adrenergic blockade and to stimulation of pulmonary vascular histamine receptors.⁶⁶ Unfortunately, responses to tolazoline are unpredictable and nonselective, and no consistent clinical benefit has been convincingly demonstrated.

Perhaps the most promising pharmacologic approach to pulmonary vasodilation is the administration of inhaled nitric oxide (iNO). NO is a ubiquitous, potent vasodilator that serves as the final common pathway for vascular smooth muscle relaxation induced by a wide variety of other agents with known vasodilatory properties.^{67,68} Endogenous NO is generated from L-arginine by the action of NO synthase in endothelial cells (eNOS) and diffuses to adjacent smooth muscle cells, where it promotes muscular relaxation via a cyclic guanosine monophosphate (GMP)-dependent mechanism.⁶⁹ Although smooth muscle relaxation induced by NO is not specific for the pulmonary circulation, vasodilation is limited to the pulmonary circulation because iNO is immediately scavenged and inactivated in the pulmonary bloodstream by binding to hemoglobin and forming methemoglobin. Thus, iNO is able to bind to pulmonary vascular smooth muscle cell receptors and induce relaxation before it diffuses into the capillary lumen and becomes inactivated. The fact the iNO diffuses directly to the smooth muscle cells makes this therapy ideal in the presence of endothelial cell injury, which is commonly seen in PPHN.

iNO is administered by mixing minute quantities of NO (5 to 20 ppm) into the gas mixture during mechanical ventilation. Although toxicity from methemoglobin has been suggested as a potential adverse effect, clinically significant methemoglobinemia has not been observed when NO is delivered at such low concentrations. A more significant difficulty with inhaled NO therapy is the development of tachyphylaxis, which frequently occurs after as little as 2 to 3 days of treatment.⁷⁰ Despite this potential obstacle, this novel strategy of selective delivery of a potent, nonspecific vasodilator to the pulmonary circulation represents a major new development in the treatment of pulmonary hypertension in infants.

A better understanding of the mechanisms of pulmonary vasoreactivity has suggested alternate approaches to iNO therapy for PPHN.⁷¹ Direct infusion of L-arginine provides both increased substrate for endogenous NO generation and stimulation of increased eNOS activity. Phosphodiesterase inhibitors such as sildenafil delay the degradation of both cyclic AMP and cyclic GMP, resulting in higher intracellular concentrations of these vasodilatory compounds. Sildenafil use may be limited by systemic hypotension, and studies are currently ongoing to establish the safety and efficacy of this drug in PPHN. Adenosine and ATP may also produce selective pulmonary vasodilation when infused intravenously, though their use in neonates with PPHN has not been studied.

Failure to promote pulmonary vasodilation through physiologic or pharmacologic manipulation may indicate a need to use extracorporeal techniques to reverse hypoxemia, hypercarbia, hypoperfusion, and acidosis. As discussed, ECMO has become a widely accepted therapy for refractory pulmonary hypertension associated with a variety of causes. It is important to recognize that extracorporeal support for pulmonary hypertension (or respiratory failure) is indicated only when the underlying cause is thought to be reversible.

GASTROINTESTINAL AND HEPATIC PHYSIOLOGY

- 11** Most mechanisms of physiologic control in the gastrointestinal tract are present at birth, although continued postnatal maturation results in ongoing adjustments over time. Prematurity, however, is associated with a delay in gastrointestinal function, just as it is in the cardiovascular and pulmonary systems. For example, immaturity of gastrointestinal motility and digestive enzyme activity in the preterm infant frequently results in early feeding intolerance. The functional immaturity of small-intestinal “brush-border” enzymes in premature infants has already been mentioned with respect to the particular nutritional requirements of preterm infants. Normal

intestinal motility, as measured by the appearance of migrating motor complexes, has been documented to appear by 36 to 38 weeks of gestation. Whereas 95% of term infants will pass a meconium stool within 24 hours of birth (and virtually 100% by 48 hours), it is not unusual for premature infants to have a significant delay in the passage of meconium that is dependent on the degree of prematurity.

The extraordinarily complex physiology of the gastrointestinal tract, including the control of motility, digestion, absorption, neurologic function, and enteroendocrine feedback, is beyond the scope of this chapter. Several specific topics in gastrointestinal physiology are relevant, however, because they relate to functional problems commonly encountered in pediatric patients. These topics include the physiology of gastrointestinal growth and adaptation, the pathophysiology of inadequate gastrointestinal length (short-gut syndrome), and neonatal jaundice.

Physiology of Intestinal Growth and Adaptation

To meet the needs of the growing child for energy and structural substrates, the absorptive surface area of the intestinal tract must increase along with somatic growth. At 28 weeks of gestation the small bowel measures about 100 cm and grows to 120 cm at 34 weeks to reach a mean length of 160 cm at full term.⁷² Postnatally, the small intestine increases from a length of about 150 to 200 cm and a diameter of about 1.5 cm at birth to a length of 600 to 800 cm and a diameter of 4 cm at maturity. Further growth and maturation of the villous architecture and the development of *plicae circulares* increase the total absorptive surface area from approximately 900 cm² to 7,500 cm² over the same period.⁷³

After growing to full length in childhood, the small intestine enters a state of dormancy and remains quiescent unless some major change occurs. Following massive intestinal resection, various adaptive responses occur in the small intestine; these responses are designed to enhance the absorptive function of the remaining bowel. These adaptive changes include an increase in diameter, an increase in the number and size of the *plicae circulares*, and epithelial hyperplasia manifested as increased villous height and crypt depth. These changes augment the absorptive surface area significantly, but they do not constitute a physiologically equivalent substitute for intestine of normal length and caliber. The markedly dilated, adapted intestine displays abnormal motility as a result of muscular hypertrophy and an inability to sustain normal peristalsis by coaptation. These dyskinetic contractions do not provide consistent, unidirectional flow and, therefore, allow stasis and bacterial colonization of the proximal intestine.

Although the factors governing stimulation of intestinal growth and adaptation are poorly understood, it is becoming increasingly clear that trophic stimulation from both enteroendocrine mediators and intraluminal substances is necessary. The gastrointestinal mucosa is richly populated with a variety of peptide-secreting enteroendocrine cells that produce local signaling and mediator molecules in response to specific stimuli (Fig. 103.12). Some of these enteroendocrine peptides are expressed only during fetal development. Virtually every known postnatal enteroendocrine cell is present and functionally mature at term.⁷⁴ The levels of many of these peptides rise sharply in the first days of life in fed infants, but not in fasting infants.⁷⁵ The observation that intestinal growth and maturation are inhibited by withholding enteral feeds suggests that enteroendocrine stimulation is one of the processes responsible for normal postnatal intestinal growth. Glucagon, glucagon-like peptides 1 and 2, and gastrin are present in the fetal and neonatal gut, and appear to be leading candidates for the principal enteroendocrine mediators of epithelial proliferation and

FIGURE 103.12. Distribution of selected enteroendocrine and neuroendocrine (asterisks) cells and their products in the proximal gastrointestinal tract. (Adapted from Magnuson DK, Schwartz MZ. In: Oldham KT, Colombani PM, Foglia RP, eds. *Surgery of Infants and Children*. Philadelphia, PA: Lippincott-Raven; 1997.)

overall gut growth, both by direct stimulation and through generation of other mediators such as insulin.^{76–78} Recent studies reveal members of the PACAP (pituitary adenylate cyclase-activating peptide)/glucagon family to be involved in gastrointestinal signaling and growth regulation. This group of related neuropeptides is found throughout the intestine. Like vasoactive intestinal peptide (VIP), PACAP is a potent vasodilator. To date, there is no evidence that VIP or PACAP administration is directly trophic for small bowel after resection or injury.⁷⁹

Direct stimulation of mucosal growth by luminal nutrients plays a major role in intestinal adaptation. The fact that villous height and absorptive capacity are greatest in the proximal jejunum and gradually decrease through the remaining jejunum and ileum suggests that progressive depletion of luminal nutrients results in relatively diminished growth of the distal intestine. Reciprocal transposition of ileal and jejunal segments results in hypertrophy of the proximally transposed ileal segment and atrophy of the distally transposed jejunal segment. The “underdevelopment” of the distal small bowel may be viewed, to a certain extent, as built-in reserve potential.

In various experimental models, adaptive growth will not occur after resection unless some level of luminal nutrition is provided. Studies in animal models have shown that complex nutrients that require enzymatic degradation (e.g., long-chain fatty acids, disaccharides, and complex proteins) are more potent stimulators of growth than are more elemental nutrients.^{80–82} This effect may result from the trophic properties of pancreaticobiliary secretions, which are stimulated by complex nutritional substrates. The amino acid glutamine is the preferred energy substrate for enterocytes and a necessary constituent of growth-promoting enteral nutrition formulas. It is not clear whether glutamine acts in a permissive fashion only by providing energy substrate for growth or whether it also has trophic properties separate from its energy content. Intravenous glutamine administration can preserve intestinal mucosal health

in the absence of enteral glutamine, but whether it can promote long-term gut adaptation and growth also is not known. Epidermal growth factor (EGF), present in duodenal and biliary secretions, and growth hormone are both potent growth stimuli. The administration of enteral glutamine and EGF (or growth hormone or both) may have a therapeutic benefit in stimulating intestinal growth after bowel resection.

Clinical Aspects of Short-gut Syndrome

Although intestinal growth is commonly taken for granted in health, its importance is brought into sharp focus by conditions in which inadequate intestinal length causes malabsorption and malnutrition: the short-gut syndrome. This syndrome usually occurs after massive intestinal resection for a variety of diseases. The most common causes in the neonatal period are necrotizing enterocolitis and midgut volvulus, although gastroschisis also may be associated with decreased intestinal length in the absence of resection.^{83,84} In older children, volvulus and inflammatory bowel disease predominate.⁸⁵ The extent of resection likely to result in short-gut syndrome is difficult to quantify and is influenced by patient age, site of intestinal loss, and status of the ileocecal valve (ICV). It is commonly held that a term newborn who retains at least 25 cm of small intestine with an intact ICV, or 40 cm without an ICV, has a reasonable potential for resuming full enteral feedings at some point. In older patients, loss of 75% to 80% of intestinal length may be tolerated as long as the ICV is preserved.

The loss of intestinal surface area diminishes absorptive capacity, brush-border digestive enzyme activity, and enteroendocrine mediator production. These deficiencies all lead to malnutrition and weight loss. Unabsorbed sugars pass through to the colon and produce an osmotic diarrhea. Presentation of undigested carbohydrates to the colon also provides fuel for bacterial proliferation. The bacteria metabolize the undigested sugars to lactate and short-chain fatty acids, which stimulate colonic secretion of water and electrolytes. Thus, a secretory diarrhea exacerbates the osmotic one. After ileal resections, bile salt recirculation is impaired and bile salts reach the colon, providing more bacterial fuel and further stimulating the secretory diarrhea. Bile salt wasting eventually depletes the hepatic bile salt pool, resulting in fat malabsorption and steatorrhea, and leading to lithogenic bile and gallstones. Extensive ileal resections also result in impaired absorption of vitamin B₁₂ and the fat-soluble vitamins A, D, E, and K.

Bacterial overgrowth in the residual small intestine occurs in most patients with short-gut syndrome. It is related primarily to the loss of the ICV and reflux of colonic bacteria into the small intestine. Overgrowth also is promoted by stasis and hypomotility, which occur in adapted, dilated, dyskinetic intestine. Bacterial overgrowth in the proximal intestine leads to further increases in carbohydrate, protein, and fluid and electrolyte loss caused by diarrhea.

Gastric hypersecretion of fluid and acid is well documented in short-gut syndrome. Acid hypersecretion has been linked to hypergastrinemia, possibly because of the loss of somatostatin and gastrin-inhibiting peptide production. Gastric hypersecretion results in peptic complications, reduced enzymatic digestion caused by low intraluminal pH, and further exacerbation of diarrhea.

Management of short-gut syndrome is complex and may include any combination of the following: parenteral nutrition, limited enteral feeding with easily absorbed substrates (glucose polymers, medium-chain triglycerides, protein hydrolysates), judicious enteral exposure to trophic substrates (complex carbohydrates, intact protein, long-chain triglycerides, and glutamine), antibiotic suppression of bacterial overgrowth, supplementation of vitamins and minerals, and control of diarrhea with antimotility agents. Clinical trials have not demonstrated any benefit with respect to enhanced intestinal

adaptation from the intravenous administration of glutamine or growth hormone.⁸⁶ Surgical treatment of short-gut syndrome by intestinal lengthening procedures and transplantation has been disappointing. In contrast, recent advances in small-bowel transplantation have resulted in improved 5-year patient survivals of 60% to 70% at centers of excellence.^{87,88}

Long-term parenteral nutrition, as it is applied in many patients with short-gut syndrome, is associated with numerous complications. Among these are catheter-related sepsis, growth failure, metabolic disorders, bone disease, and, most importantly, parenteral nutrition-associated liver disease (PNALD). PNALD is characterized by steatosis, cholestasis, hepatic fibrosis, and ultimate progression to biliary cirrhosis, portal hypertension, and end-stage liver disease. The reported incidence of PNALD varies greatly and is reported to be up to 30% in children on long-term parenteral nutrition and almost 90% in infants with similar risk exposure. The incidence of PNALD in neonates receiving parenteral nutrition ranges from 14% after 2 to 4 weeks and reaches 72% for those receiving parenteral nutrition for more than 100 days. The risk for PNALD seems to correlate inversely with birthweight.⁸⁹

Currently, parenteral lipid emulsions contain safflower and soybean oils. The administration of those plant oils may play a role in the onset of liver injury. Studies indicate that fish oil-based lipid emulsions provide a promising alternative, leading to dramatic reduction of PNALD in children receiving long-term parenteral nutrition. Due to the high concentrations of omega-3 poly-unsaturated fatty acids, administration of fish oil modulates the inflammatory response by reducing levels of proinflammatory cytokines.⁹⁰⁻⁹²

Neonatal Jaundice

Hepatic function in the older child is essentially the same as in the adult. In the neonatal period, however, liver function may be altered in a number of ways by hepatocyte immaturity. Although fetal hepatocytes begin to manifest synthetic capabilities early in gestation, the quantitative capacity to produce, modify, and detoxify various substances develops gradually and is often incompletely developed at birth, particularly in premature infants. This functional immaturity affects a range of processes, including glycogen metabolism and the biotransformation of many drugs, but most notably it affects the excretion of bilirubin.

Bilirubin Metabolism. Bilirubin is produced by the degradation of heme-containing compounds, primarily hemoglobin from senescent red blood cells, but also myoglobin, cytochromes, catalases, and other molecules. Because infants have a relatively greater red cell mass than adults, as well as a shorter red cell life span and higher turnover, bilirubin production is proportionately greatest in the first weeks of life. The conversion of heme to bilirubin occurs in reticuloendothelial cells in the liver, spleen, and elsewhere. In the first step, the ring structure of heme is opened by the oxidative removal of a carbon atom through heme oxygenase, which also releases a reduced iron atom. The resulting product, biliverdin, is a linear molecule that is further reduced by biliverdin reductase to bilirubin. Bilirubin is held in a tightly folded configuration by extensive hydrogen bonding, resulting in a highly hydrophobic and insoluble molecule. As such, transport of bilirubin from sites of production to the liver for excretion requires binding to albumin as a carrier molecule.

Bilirubin is extracted from hepatic sinusoidal blood and transported by a specific membrane carrier protein into the hepatocyte, where it is attached to the cytoplasmic carrier protein ligandin (glutathione S-transferase). Within the cytoplasm, bilirubin is conjugated with glucuronic acid by bilirubin glucuronosyltransferase (BGT) to form bilirubin monoglucuronides (BMGs) and diglucuronides (BDGs). Both BMGs

and BDGs then are transported into the bile canaliculi and excreted via the bile ducts into the duodenum. Normally, a small amount of conjugated bilirubin is found in the blood because of back-diffusion across the sinusoidal membrane. In pathologic states where the excretion of BMGs and BDGs cannot keep pace with production, serum levels of conjugated bilirubin rise. Hepatocyte excretion of BMGs and BDGs is the rate-limiting step in bilirubin clearance after 1 week of age, before which time conjugation of bilirubin is rate limiting because of diminished activity of BGT.

Within the intestinal lumen, bilirubin conjugates can have several fates. Most are metabolized by resident bacteria into a variety of compounds, including the urobilinogens and the urobilinoids, which are excreted in the feces. The conversion of conjugated bilirubin into urobilinoids prevents the reabsorption, or enterohepatic recirculation, of bilirubin. Other bacteria, as well as mucosal cells, contain β -glucuronidase capable of deconjugating BMG and BDG. Deconjugated bilirubin is hydrophobic and easily reabsorbed across the epithelial barrier and back into the circulation. Neonates are particularly susceptible to bilirubin reabsorption that results from increased levels of endogenous β -glucuronidase and decreased bacterial flora. The relative paucity of resident bacteria results in less successful conversion of bilirubin conjugates to urobilinoids, whereas the increased activity of β -glucuronidase deconjugates the bilirubin. Meconium contains a high concentration of conjugated bilirubin, which readily undergoes deconjugation if impaired motility delays its excretion.

Neonatal Hyperbilirubinemia. Transient, unconjugated hyperbilirubinemia is a ubiquitous finding in neonates and represents a normal stage in early postnatal life. For this reason, it is often referred to as physiologic jaundice. The exact cause of physiologic jaundice is unclear, but it appears to involve a combination of increased enterohepatic circulation of bilirubin and decreased BGT activity.⁹³ Both the duration and magnitude of the hyperbilirubinemia are variable but, in general, plasma levels of unconjugated bilirubin peak at about 5 to 6 mg/dL at 3 days of life and resolve by 7 to 10 days in healthy term infants.

In addition to physiologic jaundice, numerous conditions are associated with more severe unconjugated hyperbilirubinemia in the early postnatal period. These include breast-milk jaundice, hemolytic diseases (ABO or Rh incompatibility, hemoglobinopathies), reabsorption of extravascular blood, neonatal hepatitis, inborn errors of metabolism, and sepsis. Unconjugated hyperbilirubinemia can cause both a reversible encephalopathy and an irreversible neurologic injury termed *kernicterus*. The predilection of unconjugated bilirubin for neural tissue is related to its nonpolar structure, which makes it highly hydrophobic and lipophilic. Deposition of bilirubin in the basal ganglia and cranial nerve nuclei is the most common pathologic feature, although clinical manifestations include a wide variety of cognitive, developmental, motor, and sensory dysfunction. The risks of neurologic injury are related to peak sustained bilirubin levels; kernicterus is likely when sustained plasma levels exceed 30 mg/dL and is virtually unknown when levels do not exceed 20 mg/dL. Between 20 and 30 mg/dL, the incidence of reversible encephalopathy is greatest, but increasing risk of kernicterus is a concern.

Indications for intervention include early onset or prolonged duration of jaundice and exaggerated absolute levels of unconjugated bilirubin. The precise level at which therapeutic intervention is considered depends on postnatal and gestational age, weight, and presence of comorbidity, and is the subject of considerable debate. First-line therapies include stimulation of intestinal motility by oral feeding and rectal stimulation to promote the passage of meconium and reduce enterohepatic circulation. When levels become high or sustained enough to elicit genuine concern, the treatment of choice is phototherapy. Light in the blue spectrum with wavelengths of 420 to 480 nm is absorbed by unconjugated bilirubin. The absorbed energy alters

the double-bond structure of bilirubin in a process termed *photoisomerization*. The new isomers are less capable of forming internal hydrogen bonds and, therefore, become unfolded and more polar. This configurational change makes them more soluble, promotes their mobilization from central nervous system tissues, and allows their excretion in the bile without further conjugation. When extremely high levels of bilirubin are encountered and phototherapy is deemed insufficiently rapid, exchange transfusion provides the most reliable method of rapidly reducing serum bilirubin levels into a nontoxic range.

In contrast to unconjugated hyperbilirubinemia, elevation of serum conjugated bilirubin is always pathologic and mandates expeditious evaluation. The presence of isolated conjugated hyperbilirubinemia in the first weeks of life usually suggests the presence of a condition associated with reduced bile excretion. These include extrahepatic biliary atresia, Alagille syndrome (arteriohepatic dysplasia or intrahepatic biliary hypoplasia), nonsyndromic intrahepatic bile duct paucity, Byler syndrome (progressive familial intrahepatic cholestasis), choledochal cyst, and TPN-related cholestasis. Not all episodes of conjugated hyperbilirubinemia result from biliary obstruction, however. Because hepatocyte excretion of BMGs and BDGs is rate limiting after the first week of life, increased bilirubin loads generated by hemolysis or reabsorption may result in the production of bilirubin conjugates at a rate exceeding the hepatocyte's ability to excrete them into the canaliculi. Intracellular buildup results in back-diffusion of conjugated bilirubin into the sinusoidal and systemic circulation.

CHAPTER 104 ■ FETAL INTERVENTION

GEORGE B. MYCHALISKA AND DARRELL L. CASS

KEY POINTS

- 1 Four fetal conditions clearly benefit from fetal intervention: congenital cystic adenomatoid malformation, fetal sacrococcygeal teratoma, a fetus with airway obstruction from a giant neck mass or laryngeal atresia, and twin-to-twin transfusion syndrome.
- 2 Any fetal therapy requires (a) accurate diagnosis of the condition and any associated anomalies that may have an impact on outcome, (b) reliable prediction of which individual fetuses will die or suffer serious long-term morbidity without fetal intervention, and (c) that the procedure improves the outcome of the fetus with little to no maternal risk.
- 3 Preterm labor is the single biggest concern during the operation and in the postoperative period.
- 4 For a fetus with a lung mass, the only indication for fetal intervention is the presence of hydrops.
- 5 For a fetus with sacrococcygeal teratoma, increased aortic velocity, increased combined cardiac output, increased cardiac-to-thoracic ratio, a dilated inferior vena cava, or reversed end-diastolic umbilical blood flow are sensitive early predictors of impending hydrops and fetal demise; before 28 weeks' gestation, open fetal surgery and resection is the treatment of choice.
- 6 Fetal intervention may play a role in the management of a small cohort of fetuses with the most severe form of congenital diaphragmatic hernia.
- 7 An ex utero intrapartum treatment procedure is the treatment of choice for fetuses with a giant neck mass or congenital high airway obstruction syndrome.

Fetal surgery has emerged as an independent subspecialty at the intersection of pediatric surgery and maternal–fetal medicine. It is a field that has arisen from clinical necessity. Pediatric surgeons, maternal–fetal medicine specialists, and neonatologists became frustrated with the management of a number of congenital structural anomalies in which the baby died or suffered severe lifelong disability despite all efforts at postnatal treatment. With the advent of prenatal ultrasound in the 1970s, many conditions were diagnosed before birth. Fetuses were followed, and the prenatal natural history was elucidated. It became clear that a component of organ failure was acquired because of ongoing alterations in fetal development caused by the anomaly. Thus, it made sense that fetal interventions may be of benefit to correct the pathophysiology and restore normal fetal development in the hope of improving survival and decreasing morbidity.

The first successful fetal intervention was reported by Sir A.W. Liley, who successfully transfused a hydropic fetus for Rh disease.¹ Although a few attempts were made at exchange transfusion by an open technique in the 1960s, modern fetal surgery was envisioned and developed by Dr. Michael Harrison at the University of California, San Francisco (UCSF) in the late 1970s.² It was at UCSF that the concept of a fetal treatment program was developed, permitting a true multidisciplinary approach to fetal diagnosis and treatment. The first open fetal operation was performed in 1982, at which bilateral ureterostomies were performed in a 21-week-gestation fetus with obstructive uropathy.³ In the intervening years, tremendous progress has been made in the development of fetal surgery techniques, including advances in maternal–fetal anesthesia, tocolysis (prevention of preterm labor), and the development of less invasive surgical techniques. During this same period there have been significant advances in neonatal surgical critical care that has improved the outcome of fetuses with congenital anomalies. Thus, fetal surgery indications must be continually reassessed in the context of emerging prenatal and postnatal therapies. At the present time there are only three fetal conditions that show clear benefit from fetal surgery during pregnancy: congenital cystic adenomatoid malformation, fetal sacrococcygeal teratoma, and twin-to-twin transfusion syndrome. Open fetal surgery at the end of pregnancy, the ex utero intrapartum treatment (EXIT) procedure, has proven effective for treatment of giant neck masses and laryngeal atresia. The EXIT procedure has been expanded to treat conditions that result in impending respiratory failure at birth using the EXIT-ECMO (extracorporeal membrane oxygenation) strategy, but the efficacy of this technique is still unproven. Fetal interventions, including open, fetoscopic, and percutaneous, have been used to treat a number of other fetal disorders, such as congenital diaphragmatic hernia, myelomeningocele, urologic obstruction, chylothorax, and, most recently, congenital heart malformations. Many of these procedures are promising, but questions remain regarding the natural history of these disorders, selection criteria, and efficacy.

FETAL IMAGING AND PRENATAL DIAGNOSIS

1 Fetal imaging is a critical component of the decision-making process in fetal surgery. Criteria that must be met to consider fetal surgery include (a) accurate diagnosis of the condition and any associated anomalies that may have an impact on outcome, (b) reliable prediction of which individual fetuses will die or suffer serious long-term morbidity without fetal intervention, and (c) demonstration of improved fetal outcome with minimal maternal risk.

Most congenital defects can now be detected before birth with the use of high-resolution ultrasound, color Doppler, and

FIGURE 104.1. Coronal section of fetal magnetic resonance image (MRI) of a 30-week fetus with left congenital diaphragmatic hernia (CDH). The stomach (*small arrow*) and intestines are herniated into the left chest. The left lung is severely hypoplastic (*large arrow*).

fetal magnetic resonance imaging (MRI). Frequently diagnosed anomalies include diaphragmatic hernia (Fig. 104.1), congenital lung lesions (Fig. 104.2), obstructive uropathy, neural tube defects, neck masses (Fig. 104.3), congenital heart defects, and sacrococcygeal teratoma. Other surgical disorders include abdominal wall defects (gastroschisis and omphalocele), intestinal atresias, and cystic and solid abdominal masses. Although ultrasound is the predominant prenatal screening and diagnostic modality, fetal MRI has proven particularly helpful in the further evaluation of central nervous system, chest, and neck anomalies.^{4–6} Fetal echocardiography is essential in the evaluation of congenital heart disease and is also useful in evaluating abnormal cardiac function associated with other birth defects.^{7–9}

Prenatal detection and serial ultrasonographic evaluation of these disorders has enhanced our understanding of their natural history, and has significantly improved perinatal management. Pediatric surgeons familiar with the management of congenital malformations before and after birth, along with obstetricians, neonatologists, geneticists, and other specialists, participate in family counseling and together contribute to optimal maternal–fetal management. Such multidisciplinary teams may recommend that the timing, mode (cesarean vs. vaginal delivery), or location of delivery be altered. Furthermore, in rare circumstances prenatal diagnosis permits in utero treatment of the developing fetus to prevent, reverse, or minimize fetal organ injury or death. In one study, prenatal consultation led to a change in pregnancy management in 67% of 221 pregnancies, of which 11 patients (5% of total) benefited from fetal intervention.¹⁰

Although most congenital anomalies are best managed with the use of appropriate medical and surgical therapy after delivery at term, rare fetal anomalies may benefit from surgery before birth. The innovations required for fetal surgery include the development of new surgical, anesthetic, and tocolytic techniques, as well as the resolution of such ethical issues as maternal safety and future maternal reproductive potential.^{11–13}

FIGURE 104.2. Coronal section of a fetal magnetic resonance image (MRI) of a 24-week fetus with a large left lung mass (bronchopulmonary sequestration). The left diaphragm is flattened and there is moderate dextroposition of the heart. A large vessel is seen coming from the low thoracic aorta (arrow). The congenital cystic adenomatoid malformation volume ratio (CVR) was 1.96; however, hydrops did not develop and the baby “grew around” the mass.

FIGURE 104.3. Coronal section of a fetal magnetic resonance image (MRI) of a 31-week fetus with a large left neck lymphatic malformation. The mass extends to the apex of the left chest (arrow). There is moderate left-to-right tracheal deviation. This fetus was delivered with an ex utero intrapartum treatment (EXIT) procedure.

MATERNAL–FETAL RISKS

Fetal surgery is unlike all other surgical specialties in that it involves two patients; the surgeon must operate on a healthy maternal patient to fix a disease in the affected fetus. This paradigm presents challenging moral and ethical conflicts that must be considered and balanced in each circumstance. Chervenak and McCullough¹⁴ and others have helped to provide an ethical framework within which fetal surgery should exist. The keys to this framework are that (a) the fetal operation has significant chance of being lifesaving or of preventing serious or irreversible disease in the fetus; (b) the procedure involves low mortality and morbidity risk to the fetus; and (c) the operation has very low mortality and morbidity risk to the pregnant woman, including risks to future pregnancies. In light of these considerations, a number of contraindications to fetal intervention exist, including chromosomal abnormalities, the presence of other major anomalies, and significant maternal comorbidities.

There are significant maternal and fetal risks associated with fetal surgery that must be weighed for each patient. For the fetus, there is risk of preterm delivery, fetal death, or survival with poor outcome. Most indications for fetal surgery, however, are ones in which the fetus would die without it, and therefore the risk-to-benefit ratio is very favorable. For those interventions aimed at improving the outcome of fetuses with nonlethal conditions, the risk-benefit ratio is much more difficult to assess. For example, the efficacy of fetal surgery for spina bifida is being evaluated with a prospective randomized trial.¹⁵

The risks and benefits to the mother depend on the invasiveness of the fetal surgical operation. In any intervention, benefits to the mother include the psychological reward from doing everything possible to improve the condition of the unborn baby. In select cases, there is physiologic benefit in preventing the possibility of “mirror syndrome,” a pre-eclampsialike condition in which the mother’s condition “mirrors” that of a sick or dying fetus.¹⁶ In the presence of this syndrome, fetal surgery is contraindicated and urgent fetal delivery is important to ensure maternal health. For the mother, fetal surgery adds the discomfort of one or two operations that would not have been required otherwise. For mothers who have hysterotomy other than low transverse, and for all mothers having open fetal surgery, there are theoretical risks to subsequent pregnancies and future fertility. When maternal fertility following fetal surgery was studied, however, it was found that 32 of 35 mothers were able to achieve successful subsequent pregnancies and 31 live births resulted.¹¹ Furthermore, if a classic cesarean section is performed during open fetal surgery, subsequent deliveries must be performed by cesarean section. Specific complications resulting from a classic cesarean section in subsequent pregnancies include uterine dehiscence and uterine rupture.¹⁷ Postoperatively, nonhydrostatic pulmonary edema may occur in the mother. This problem was more prevalent in the early experience of open fetal surgery, but it still persists. In a recent trial reported by Harrison et al.,¹⁸ 3 of 11 mothers developed pulmonary edema and required oxygen after fetal surgery. In each of these patients the symptoms were mild and resolved within 48 hours. The cause of this phenomenon remains unclear, but is likely related to uterine manipulation and the release of prostaglandins or thromboplastins that alter maternal lung vascular permeability.¹⁹ As with all obstetric surgery, blood loss may be significant and mothers undergoing fetal surgery occasionally require blood transfusion.²⁰ Chorioamniotic membrane separation and preterm labor remain the Achilles’ heel of fetal interventions.^{21,22} Surgical approaches that involve a smaller hysterotomy and more minimally invasive techniques appear to lower these risks.²³ Specifically, fetoscopic and percutaneous approaches

lessen the maternal and fetal risks.²⁴ These techniques allow vaginal delivery after fetal surgery and appear to decrease the incidence of preterm delivery.²⁵ Thus far, no maternal deaths have occurred at the major fetal surgery centers in the United States and Europe.

SURGICAL TECHNIQUES: OPEN, FETOSCOPIC, AND PERCUTANEOUS APPROACHES

Numerous technical aspects of fetal surgical procedures have evolved over 30 years of experimental and clinical work and have been reviewed in detail elsewhere.^{26–29} The comprehensive care of the fetal surgery patient is labor intensive and requires multidisciplinary cooperation between all team members. In the operating room, the leader of the fetal surgery team is either a pediatric surgeon or maternal–fetal medicine specialist with specific training in fetal surgical techniques. The leader should be chosen depending on the procedure and specific expertise.³⁰ Responsibility for the patient's anesthesia is shared between an obstetric anesthesiologist for the mother and a pediatric anesthesiologist for the fetus. Both anesthesiologists should have special expertise in maternal–fetal anesthesia and work together as a team. A high-resolution ultrasound machine with color and enhanced Doppler is essential and used throughout the procedure to assess fetal and placental position; monitor fetal heart rate, cardiac function, and volume status; and assess amniotic fluid levels.³¹ A pulse oximetry probe is placed on the fetal hand to assess fetal oxygen saturation and continuous heart rate. A peripheral intravenous

catheter is often placed in the fetus for fluid, blood, and medication delivery. A surgical nursing team trained in the specific aspects of fetal surgical procedures and instrumentation is mandatory.

Open fetal surgery is performed with general and epidural anesthesia. Epidural delivery of a fentanyl/bupivacaine mixture provides optimal postoperative analgesia and minimizes uterine irritability. Intraoperatively, inhaled isoflurane titrated to an end-tidal concentration of 2% or higher is used to achieve uterine relaxation, which is critical to successful outcomes. Because of the risk of postoperative pulmonary edema, the mothers are fluid restricted during these procedures and receive as little as 500 mL of crystalloid. The patient is positioned supine with a roll under the right side to avoid compression of the inferior vena cava by the gravid uterus. The uterus is exposed through a low transverse abdominal incision. If the placenta is positioned posteriorly, subcutaneous flaps and a midline incision from the umbilicus to the pubis permit adequate uterine exposure. In cases of an anterior placenta, the fascia and rectus muscles are divided transversely so that the uterus can be tilted forward for a posterior hysterotomy. A large abdominal ring retractor is useful for abdominal wall retraction. After uterine relaxation is confirmed by palpation, the orientation of the fetus and placenta is confirmed by ultrasound. For open fetal surgery during pregnancy, a classical cesarean section incision is made. For the EXIT procedure, it is preferable to perform a low transverse hysterotomy. Two opposing traction sutures are placed with ultrasound guidance to provide hemostasis and to secure the fetal membranes to the uterine wall. The myometrium is then incised, and a hemostatic uterine stapler is used to open the uterine wall in both directions. A rubber catheter connected to a rapid infuser is inserted

FIGURE 104.4. Fetal surgery of a hydropic 24-week fetus with a large left lung mass. **A:** Intraoperative ultrasound to locate the placenta and fetus. **B:** Uterine stay sutures are elevated to facilitate the use of the uterine stapler. **C:** The mass has been removed and the remaining normal left lung is evident. A bolus of crystalloid is given into the umbilical vein, and the chest is being closed.

into the amniotic space to replace egress of amniotic fluid with warmed Ringer lactate. Infusion of warmed fluids is critical to maintain fetal temperature and amniotic volume and to minimize the risk of uterine contractions and umbilical cord compression (Fig. 104.4).

One of the unique requirements of fetal surgery is that the surgeon must operate on the fetus and then return the fetus to the amniotic environment in such a way as to minimize disturbance to the continuing pregnancy. The uterine closure must have adequate strength to prevent rupture, must have membrane reapproximation to prevent amniotic fluid leakage, and must limit risks for preterm labor or future infertility. Currently, the uterus is closed in two layers using an outer layer of full-thickness 0 polydioxanone (PDS) retention sutures and an inner running layer of 2–0 PDS to close the myometrium and membranes. Before the closure is complete, the rapid infuser is used to restore amniotic volume and administer antibiotics. An omental pedicle is secured over the hysterotomy to seal any small leaks from the full-thickness sutures.

3 Preterm labor is the single biggest concern during the operation and in the postoperative period. The mother receives a 50-mg indomethacin suppository 4 hours before surgery, and remains on indomethacin for 48 hours postoperatively. Daily echocardiography is essential; if there is evidence of patent duct arteriosus (PDA) restriction, then the indomethacin is stopped. During the operation terbutaline or nitroglycerin infusion can be used to help control uterine irritability and enhance relaxation. During closure of the hysterotomy, the mother is given a 6-g bolus dose of magnesium sulfate followed by a continuous infusion of 2 to 4 g/h. Postoperatively the mother is observed in an intensive care unit (ICU) setting for close monitoring for pulmonary edema, fluid management, and uterine irritability. The magnesium sulfate is continued for 48 to 72 hours with close monitoring of magnesium levels and signs of toxicity. On the second to third postoperative day, usually the magnesium and indomethacin can be weaned, and the patient is converted to subcutaneous terbutaline or oral nifedipine. The patient is maintained on bedrest until the time of delivery. Postoperatively, daily ultrasound examinations help to assess the ductus arteriosus, amniotic fluid index (estimate of fetal urine output or of amniotic fluid leak), and fetal movement (marker of fetal well-being).

Fetoscopic surgery has been used most recently to permit a number of fetal surgical interventions, such as tracheal occlusion, laser ablation of communicating vessels in twin-to-twin transfusion syndrome, and fetoscopic ablation of posterior urethral valves for fetuses with obstructive uropathy. Initially, these procedures were performed by exposing the uterus through a maternal laparotomy. More recently, surgeons have placed trocars percutaneously into the uterus through the intact maternal abdominal wall. Specially designed fetoscopic instruments have been developed that have allowed for single-port procedures.³² Visualization during fetoscopy requires continuous irrigation through the fetoscope. This permits maintenance of uterine fluid volume, avoids risk of air embolus with gas distention of the uterus, ensures a continuously washed operative field, improves visibility by exchanging the cloudy amniotic fluid with lactated Ringer solution, and keeps the fetus warm.

RATIONALE AND OUTCOME OF FETAL SURGERY FOR SPECIFIC CONGENITAL ANOMALIES

Lung Malformations

Congenital cystic adenomatoid malformation (CCAM) and bronchopulmonary sequestration are the most common congenital lung malformations, and the most common fetal tho-

racic lesions that may benefit from fetal intervention.³³ The incidence of these lesions has been estimated at 1 in 25,000 to 35,000 pregnancies³⁴; however, current referral patterns to fetal therapy centers suggest they may occur more frequently. Grossly, a CCAM is a discrete, space-occupying intrapulmonary mass that contains variable-sized cysts. These lesions do not function in normal gas exchange; however, airspaces within these masses communicate with the tracheobronchial tree. Histologically, CCAM is distinguished from other lesions and normal lung by (a) polypoid projections of the mucosa, (b) an increase in smooth muscle and elastic tissue within cyst walls, (c) an absence of cartilage (except that found in “entrapped” normal bronchi), (d) the presence of mucus-secreting cells, and (e) the absence of inflammation. In contrast, bronchopulmonary sequestrations (BPSs) (intralobar or extralobar) are masses of nonfunctioning lung tissue that are supplied by an anomalous systemic artery and do not have connection to the native tracheobronchial tree. The pathogenesis of both lesions is unknown, but they are thought to arise during the fifth to sixth week in embryonic development, and may result from abnormalities in growth signals between the branching airway epithelium and pulmonary mesenchyme.^{35,36} Congenital lung lesions are commonly diagnosed by prenatal ultrasound as an echogenic solid, or cystic and solid thoracic mass. Not infrequently, these lesions may be seen to have a systemic blood supply on Doppler ultrasound. Although CCAM and BPS have been distinguished prenatally in the past by the presence or absence of a systemic vessel, it is now recognized that these lung lesions represent a continuum of pulmonary maldevelopment and there are lesions that have clinicopathologic features of both.^{37,38} Fetal MRI may enhance diagnostic accuracy in examining these lesions and distinguishing them from other thoracic abnormalities, such as congenital lobar emphysema, bronchial atresia, bronchogenic cyst, and congenital diaphragmatic hernia.^{39,40}

The natural history and clinical spectrum of these anomalies are variable, but they appear to depend mostly on the size of the mass and the secondary physiologic derangement. The growth of CCAMs usually plateaus between 25 and 28 weeks, at which time the fetus appears to grow around the lesion. The vast majority of small to moderate-sized CCAMs remain asymptomatic during fetal life. Approximately 15% of CCAMs will shrink significantly before birth.⁴¹ In contrast, large lesions represent 5% to 10% of CCAMs and may produce significant mass effect, which can lead to pulmonary hypoplasia, impaired fetal swallowing and polyhydramnios, and impaired venous return and heart failure. Congestive heart failure in the fetus, known as nonimmune fetal hydrops, is defined by the presence of skin or scalp edema, or by fluid accumulation in one or more serous cavities (ascites or pericardial or pleural effusions). The risk of hydrops appears to depend on the size and rate of growth of the mass, and results from compression of the superior vena cava and impaired venous return.⁴² It has been demonstrated that hydrops is a harbinger of fetal demise, and is associated with near 100% mortality.⁴³ Rarely, hydrops is due to a tension hydrothorax from extralobar sequestration.⁴³ As a prognostic factor, the CCAM volume ratio (CVR) has been developed to correlate the relative size of these lesions with fetal and postnatal outcome.⁴⁴ In one series in which 58 fetuses with a lung mass were followed prospectively, 75% of fetuses (12 of 16) with a CVR greater than 1.6 developed hydrops, whereas only 17% (7 of 42) with a CVR of 1.6 or less had this complication. However, the CVR was not predictive of hydrops if a CCAM had a dominant cyst, which may enlarge at an unpredictable rate.

4 For a fetus with a lung mass, the only indication for fetal intervention is the presence of hydrops. Most commonly, hydrops occurs in the period of rapid growth of these lesions between 19 and 26 weeks' gestation.^{33,43,44} Fetuses with a lung mass should be followed closely. It is recommended that those with a CVR less than 1.6 receive weekly ultrasound up to about

28 weeks' gestation, whereas those with a CVR greater than 1.6 should be examined as frequently as two to three times per week. If signs of hydrops appear, the treatment options include percutaneous placement of a thoracoamniotic shunt for lesions with a dominant cyst, and open fetal thoracotomy and mass resection for more solid lesions. Use of the laser or radiofrequency ablation to debulk a large CCAM cannot be recommended now because of technical limitations and inability to control energy distribution and postprocedure swelling.^{45,46}

Fetal surgery for fetal lung masses requires open hysterotomy (Fig. 104.4). Intraoperative echocardiography is critical to assess fetal intravascular volume and right ventricle filling. These fetuses have tamponade physiology and generally benefit from a fluid bolus before thoracotomy. A relatively large thoracotomy is required to permit adequate exposure, and the mass is delivered slowly to prevent rapid decreased cardiac venous return. At resection, the presence of a systemic vessel must be considered.

The first successful open fetal surgery for CCAM was reported in 1990 by Harrison et al. at UCSF.⁴⁷ Since then, there have been reports of 22 open fetal resections of lung masses, with 50% survival.³³ Delays in referral and intervention, the presence of maternal "mirror" syndrome, preterm labor, chorioamnionitis, and technical difficulties associated with the procedure have limited outcomes in half of the cases. Recent evidence suggests that administration of maternal steroids may reverse the pathophysiology of hydrops, but this strategy requires further validation.^{48,49}

Sacroccygeal Teratoma

Sacroccygeal teratoma (SCT) is the most common neonatal tumor, with an incidence of 1 in 35,000 live births.^{50,51} Thought to arise from totipotent somatic cells originating in the caudal cell mass, this tumor contains multiple neoplastic tissues that lack organ specificity, are foreign to the sacroccygeal region, and are derived from all three germ layers. The postnatal mortality of SCT is low, despite that about 10% of neonatal lesions are malignant. However, the prenatal mortality from SCT is greater than 50%. The causes of death in fetal SCT are multifactorial, but primarily involve dystocia with tumor rupture and bleeding at the time of delivery, or high-output cardiac failure and hydrops from high blood flow within the mass.⁵² The evolution of high-output cardiac failure before the development of placentomegaly and hydrops in a fetus with SCT is the sole indication for fetal surgical intervention. Furthermore, SCT may lead to maternal mirror syndrome (Ballantine syndrome).⁵³ In this condition, the mother experiences progressive preeclampsialike symptoms, including vomiting, hypertension, peripheral edema, proteinuria, and pulmonary edema, caused by the release of placental vasoactive factors or endothelial cell toxins from the edematous placenta. This syndrome is reversed only by delivering the child and the placenta, but not by removing the SCT prenatally.

The diagnosis of SCT can be made by fetal ultrasound as early as 14 weeks' gestation.⁵⁴ The sonographic appearance may be cystic, solid, or mixed, and may demonstrate irregular echogenic patterns secondary to areas of tumor necrosis, cystic degeneration, internal hemorrhage, or calcification. Ultrasound is important to assess abdominal or pelvic extension, evidence of bowel or urinary tract obstruction, and the integrity of the fetal spine, and to document lower extremity function. Fetal MRI is helpful to delineate the anatomy and may be useful to distinguish these lesions from myelomeningocele, meconium pseudocyst, and obstructive uropathy. Fetal echocardiography and Doppler ultrasound measurements are important in the diagnostic assessment and follow-up of fetuses with these conditions. Increased aortic velocity, increased combined cardiac output, increased cardiac-to-thoracic ratio, a dilated inferior vena cava, or reversed end-diastolic umbilical blood flow

appear to be sensitive early predictors of impending hydrops and fetal demise.^{8,55} For fetuses greater than 28 weeks' gestation, these findings are an indication for emergency cesarean delivery and postnatal resection. For fetuses less than 28 weeks, open fetal surgery and resection is the treatment of choice. Minimally invasive approaches to interrupt the tumor's blood supply with radiofrequency ablation have had limited success⁵⁶ but may be alternatives for a fetus that is a poor candidate for open fetal resection.

Adzick et al.⁵⁷ reported the first successful outcome for fetal surgery resection of a fetus with a large SCT and hydrops in 1997. More recently, investigators from that center have reported 75% survival (three of four) for fetal resection of SCT. A similar high-output heart failure physiology can occur with teratomas in other locations. A fetus with a cervical teratoma and hydrops had successful fetal resection of the lesion at 24 weeks' gestation.⁵⁸

Congenital Diaphragmatic Hernia

At present, the role of fetal intervention in the management of fetuses with congenital diaphragmatic hernia (CDH) is not clear. A hole in the posterolateral diaphragm, left sided in 80% to 85% of cases, permits abdominal viscera to herniate into the chest during fetal development, resulting in pulmonary hypoplasia and pulmonary hypertension. In current practice, more than half of the infants with CDH are diagnosed before birth. At times it can be difficult to distinguish CDH from a cystic lung mass or other cystic lesions. Fetal MRI is useful to enhance diagnostic accuracy, confirm liver position, calculate lung volumes, and further exclude associated anomalies.^{6,59}

Outcome for patients with CDH varies widely, depending on the severity of disease when the disease is diagnosed.⁶⁰ The overall survival of CDH in the United States is 68%.⁶¹ Although the survival has improved in select centers,⁶²⁻⁶⁵ the morbidity of some survivors remains high.⁶⁶ Fetuses with CDH have lower survival rates than those for live-born infants or for infants presenting to a neonatal surgical center. This paradigm has been termed the "hidden mortality" by Harrison et al.,⁶⁷ and has been confirmed by multiple investigators.⁶⁸⁻⁷⁰ In 2000, Dillon et al.⁷¹ reviewed the outcomes from a large series of fetuses with CDH registered in the Northern Region Congenital Abnormality Survey in the United Kingdom. Between 1985 and 1997, 201 fetuses were evaluated for diaphragmatic problems, of which 187 had congenital diaphragmatic hernia (14 had diaphragm eventration). From this cohort, 38 pregnancies were terminated, 26 of which had "multiple abnormalities," and 14 pregnancies (7%) were complicated by spontaneous miscarriage or stillbirth. The overall 1-year survival was 37%, but for live-born fetuses the survival was 50%. Furthermore, for those live-born babies with isolated CDH, the overall survival was 59%.

Ultrasound (and more recently MRI) can be used to predict fetal CDH severity. Herniation of the liver into the fetal chest and marked lung hypoplasia as estimated by a lung-to-head ratio (LHR) less than 1.0 are strong predictors of perinatal death.^{72,73} Fetuses without liver herniation through the diaphragm have a reported survival rate between 75% and 93%, whereas those with "liver up" have a survival rate as low as 43%.⁷⁴ In a report that included evaluation of 174 patients with CDH, an LHR less than 0.9 was associated with only 13% survival, whereas survival was 68% for an LHR 0.9 to 1.2 and 88% for an LHR greater than 1.2.

For select infants with severe CDH, fetal surgery has been performed in an attempt to reverse the high mortality rate. Initially, complete in utero repair of the diaphragmatic defect was attempted.⁷⁵ This approach, however, led to fetal bradycardia and immediate death after attempts to reduce the liver from the fetal chest resulted in kinking of the ductus venosus.⁷⁶ Subsequently, in utero tracheal occlusion has been used to treat fetuses with severe CDH. It has been shown that temporary

tracheal occlusion, performed either as an open procedure or fetoscopically, can prevent the normal egress of lung fluid and enhance growth of the fetal lungs.⁷⁷ In a review of 15 patients treated by open fetal tracheal occlusion at Children's Hospital of Philadelphia (CHOP), survival was 100% for patients with right-sided defects (two of two) and 23% for patients with left-sided defects (3 of 13), compared with 0% survival for a matched group of seven infants with left-sided lesions managed by conventional treatment alone. Endoscopic approaches to fetal tracheal occlusion, termed "fetoscopic" or "FETENDO," showed more promising outcomes.⁷⁸ Recently, however, Harrison et al.¹⁸ from UCSF reported results from a National Institutes of Health (NIH)-sponsored, prospective randomized trial that compared fetoscopic tracheal occlusion with standard postnatal care for fetuses with left-sided CDH, "liver up," and an LHR less than 1.4. Twenty-four fetuses were randomized, but at this point the trial was stopped because of an unexpected high survival in the standard treatment group and the expectation that fetal therapy in this design would show no benefit. In this study of fetuses with liver-up CDH, the overall 90-day survival rate was 75%, a number much higher than those reported previously. Whereas 8 of 11 (73%) fetuses survived following fetoscopic tracheal occlusion, 10 of 13 (77%) survived with postnatal treatment alone, thus showing no benefit to fetal therapy in this study. As expected, a striking difference in the gestational ages was noted between the two groups. Whereas the standard treatment group delivered at a mean gestation of 37 weeks, the tracheal occlusion group delivered at a mean of 30.8 (range of 28 to 34) weeks' gestational age. Although fetoscopic tracheal occlusion likely had an effect on lung growth, this response may have been limited by preterm labor, early delivery, and associated lung immaturity. As has been demonstrated in the treatment of other conditions, chorioamniotic membrane separation and preterm labor limit outcomes from fetal surgery.^{21,22} The lack of benefit from fetal therapy may also result from the excellent outcomes that were achieved in the control group. These results certainly suggest that a standardized protocol involving prenatal steroids and expert pre- and postnatal care may improve outcome for fetuses with severe CDH.

Deprest et al. from Europe²³ have reported initial results from the fetoscopic tracheal occlusion (FETO) task group, an ongoing prospective multicenter study of patients with severe CDH treated by fetoscopic approaches. This study involves patients with isolated CDH, liver up, and an LHR of less than 1.0. Using epidural anesthesia, a single 10-French cannula is placed through the intact maternal abdominal wall and uterus. A specially designed fetoscope is placed, the fetus is endotracheally intubated, and a detachable balloon is deployed in the midtrachea of these patients. Initially, fetuses were delivered by an EXIT procedure; however, more recently investigators have performed a second fetoscopic procedure later in gestation to remove the balloon and permit vaginal delivery. Results from the first 21 patients treated between April 2002 and October 2003 showed 47% overall survival in the treatment group, with a mean gestation of 34 weeks. In comparison, a matched cohort of fetuses with severe CDH had only 8% survival (1 of 12). More recently, Deprest reported results from the use of FETO in 210 patients. The procedure was performed at a median gestational age of 27 weeks. Although spontaneous preterm prelabor rupture of membranes occurred in 47% of patients, the median gestational age at delivery was 35.3 weeks. The authors estimated that in fetuses with left CDH treated with FETO, the survival rate increased from 24% to 49%.²⁵ The results from this trial are promising but still limited due to a lack of a randomized design and lack of standardized, centralized postnatal care in the control group of fetuses.

6 It is likely that fetal intervention may play a role in the management of a small cohort of fetuses with the most severe form of CDH. Current work is directed at accurate identification of this cohort and optimizing minimally invasive treatment approaches.

FIGURE 104.5. A 36-week fetus with a giant right neck teratoma at ex utero intrapartum treatment (EXIT) procedure. Due to significant tracheal deviation, a tracheostomy was performed on placental support.

Fetal Surgery at the End of Pregnancy

Ex Utero Intrapartum Treatment Procedure. As an outgrowth of the fetal intervention efforts, the EXIT procedure was devised to treat fetal airway obstruction caused by large neck masses or intrinsic airway problems.⁷⁹ This approach involves a planned hysterotomy and delivery with preservation of the maternal-fetal placental circulation for oxygenation of the fetus. While on "placental bypass," up to 2 hours is available for direct laryngoscopy, bronchoscopy, endotracheal intubation, tumor resection, or tracheostomy to secure the airway (Fig. 104.5). The umbilical cord is then divided, and the fetus delivered. Indications for an EXIT procedure include the presence of a large cervical mass with evidence of airway deviation or compression. Polyhydramnios, caused by esophagus compression, is one marker for fetal tracheal compression. Recently, the tracheoesophageal displacement index (TEDI) has been described to assess the degree of tracheal deviation on fetal MRI.⁸⁰ Multiple centers have used the EXIT procedure to stabilize the airway in fetuses with large cervical tumors (e.g., teratomas or lymphatic malformations) with excellent fetal outcomes and very little additional maternal risk⁸¹⁻⁸³ (Fig. 104.5).

An EXIT procedure is the treatment of choice for fetuses with congenital high airway obstruction syndrome (CHAOS). This syndrome is usually caused by laryngeal or tracheal atresia, tracheal stenosis, or a mucosal web. A fetus with this condition develops overdistended, echogenic lungs, which may compress the mediastinum, flatten or evert the diaphragm, and cause hydrops because of compromise of venous return. Fetuses with CHAOS should be delivered with an EXIT procedure to permit tracheostomy and airway control while maintaining the maternal-fetal placental circulation. For fetuses with CHAOS who develop hydrops, early delivery or prenatal tracheostomy are treatment options, depending on gestational age.⁸⁴⁻⁸⁶

EX UTERO INTRAPARTUM TREATMENT-EXTRACORPOREAL MEMBRANE OXYGENATION

The EXIT-ECMO procedure has been developed to treat anticipated respiratory failure at birth. The rationale for this procedure is to transition from a stable intrauterine environment to ECMO while avoiding hypoxemia, barotrauma, hemodynamic

FIGURE 104.6. A 37-week fetus with severe congenital diaphragmatic hernia (CDH) delivered using the ex utero intrapartum treatment (EXIT)-extracorporeal membrane oxygenation (ECMO) procedure. The airway was secured and ECMO cannulas were placed on placental support.

instability, and acidosis. This strategy has been applied to severe CDH. Kunisaki et al. reported the largest series of 14 patients who had EXIT-ECMO for treatment of severe CDH.⁸⁷ Inclusion criteria included liver herniation, an LHR less than 1.4, percentage of predicted lung volume by fetal MRI less than 15, and/or congenital heart disease. Overall survival was 64% for this severe subset of CDH patients. Although this therapy is promising, at this time its efficacy is unproven. Variations of this procedure include EXIT-resection for lung lesions,⁸⁸ EXIT-ECMO for fetal thoracic masses,⁸⁹ and EXIT-resection-ECMO for giant chest masses⁹⁰ (Fig. 104.6).

Myelomeningocele

Myelomeningocele (MMC) was the first nonlethal anomaly to be treated by fetal surgery.^{91–93} MMC, or spina bifida, is a midline defect of the spine and spinal cord that leads to exposure of the contents of the neural canal. It is relatively common, and occurs in 1 of every 2,000 live births. The natural history of fetuses with this condition is variable, but generally mortality is low. Instead, affected newborns suffer lifelong disabilities, which include a combination of paraplegia, abnormalities in bowel or bladder control, sexual dysfunction, skeletal deformations, hydrocephalus, and mental impairment. More than 80% of fetuses with MMC can be identified before birth by maternal serum α -fetoprotein screening. Fetal ultrasound may detect the characteristic spine abnormalities as early as 16 weeks' gestation.

The rationale for fetal intervention for MMC is based on compelling evidence that associated neurologic deficits do not simply result from incomplete neurulation but rather from chronic mechanical and chemical trauma caused by exposure of the neural tissue to the amniotic environment. Support for this conclusion includes the observation that fetal leg movements decrease with advancing gestational age. Furthermore, in animal models of MMC, in utero repair leads to improved neurologic function and reversal of hindbrain herniation.⁹⁴

Human fetal interventions for MMC were initially designed to reduce intrauterine exposure of neural elements. Both fetoscopic and open techniques were attempted; however, open methods are considered the current standard. The first successful outcome of fetal surgery repair of MMC was reported by Adzick et al. in 1998.⁹¹ Since that time multiple centers have reported positive outcomes that suggest that surgical repair of

MMC before 25 weeks' gestation can preserve neurologic function, reverse the hindbrain herniation, decrease the incidence of clubfoot, and obviate the need for postnatal placement of a ventriculoperitoneal shunt compared with historical controls.^{92,93,95} No consistent improvement was seen in neurologic or bladder function, however, and these interventions did come at the cost of fetal prematurity (preterm labor) and increased maternal risk. Furthermore, lack of accurate prenatal indicators of neurologic function and absence of matched controls and long-term follow-up hamper evaluation of this approach. To better assess the merit of fetal surgery for this condition, an NIH-sponsored multicenter, prospective, randomized trial is currently under way.

Urinary Obstruction

Obstructive uropathy, one of the most common fetal structural anomalies, occurs in about 1 of 1,000 live births. Of all fetuses with urinary tract dilatation, as many as 90% do not require fetal intervention, such as those with low-pressure dilation, continued good urine output, adequate amniotic fluid volume, unilateral urinary obstruction, or advanced irreversible renal dysplasia.^{96,97} Fetuses with urethral obstruction, severe bilateral hydronephrosis, and preserved renal function may be candidates for fetal intervention. Urethral obstruction, usually caused by posterior urethral valves in a male fetus, leads to decreased fetal urine output, oligohydramnios, and eventually pulmonary hypoplasia, which is often the most important factor affecting postnatal outcome. Fetuses with oligohydramnios present in the early second trimester have mortality rates in excess of 90%.^{98,99}

Prenatal ultrasound is very accurate in the detection of fetal hydronephrosis and in determining the level of urinary obstruction. Because most of the amniotic fluid in middle and late pregnancy is the product of fetal urination, the presence of a normal amniotic fluid index implies the excretion of urine from at least one kidney. Decreasing amniotic fluid volume on serial ultrasound usually indicates deteriorating renal function. Furthermore, renal function can be assessed by the sonographic appearance of the renal parenchyma and by the laboratory analysis of fetal urine via percutaneous bladder aspiration. The presence of cortical cysts or increased echogenicity is highly predictive of renal dysplasia, but the absence of these findings does not exclude it.¹⁰⁰ Normal fetal urine chemistry includes a urinary sodium less than 100 mEq/dL, chloride less than 90 mEq/dL, osmolality less than 200 mOsm/L, and β_2 -microglobulin less than 4 mg/dL. Values greater than these suggest that the fetal kidney is unable to reabsorb these molecules and predict poor postnatal renal function.

The greatest challenge is selecting fetuses that have severe urinary obstruction yet reversible or salvageable renal function. Presently, selection criteria for fetal intervention are a male fetus less than 30 weeks' gestation with evolving oligohydramnios, normal renal function, and no associated anomalies. Fetuses older than this are best treated by postnatal approaches. If there is evidence of lung maturation, then early delivery is recommended. The goal of fetal therapy is to adequately drain the urinary obstruction and to restore normal amniotic fluid volume. Methods of urinary tract decompression include percutaneous vesicoamniotic shunt placement, fetoscopic or open vesicostomy, and fetoscopic fulguration of posterior urethral valves.^{101,102} Open fetal surgery, including vesicostomy or ureterostomy, has resulted in 50% survival, with two of eight children in one series having normal renal function.¹⁰³ Today, the most widely used and accepted means of treating bladder outlet obstruction is percutaneous insertion of a double-J vesicoamniotic shunt. Placement of a vesicoamniotic shunt is associated with 50% survival, but shunt complication rates as high as 45% may result. Direct fetoscopic ablation of posterior urethral valves holds promise for the future, though currently

limited data are available to assess selection criteria and outcomes for fetuses treated by this approach.

Twin-to-twin Transfusion Syndrome

Twin-to-twin transfusion syndrome (TTTS), present in 5% to 35% of monochorionic twin pregnancies, occurs when there is unequal sharing of the monochorionic placenta. Generally, this finding can be made on prenatal ultrasound, and often the communicating placental vessels can be characterized by Doppler. Arteriovenous anastomoses lead to a net shunting of blood from the donor to recipient. The donor twin often suffers intrauterine growth retardation, cardiac failure, and oligohydramnios, whereas the recipient twin may suffer polyhydramnios, cardiomyopathy, and fetal hydrops. The smaller twin's placental cord insertion is often marginal or velamentous, whereas the larger twin's cord inserts into the placenta centrally.¹⁰⁴ Quintero et al.¹⁰⁵ have described a staging system for this condition. In stage 1, polyhydramnios and oligohydramnios occur, but the donor bladder is still visible. In stage 2, the bladder is no longer visible, and in stage 3 abnormal Doppler signals are detected in the respective umbilical arteries or veins. Stage 4 is characterized by findings of hydrops, and stage 5 is fetal death. In addition to the Quintero staging, recent studies suggest that comprehensive cardiac assessment by echocardiography may improve patient risk stratification.⁹ Overall, TTTS before 26 weeks' gestation is associated with a high rate of fetal loss and perinatal death and a high incidence of brain damage in survivors.^{106,107} In severe forms of TTTS, perinatal mortality rates of up to 90% have been reported.¹⁰⁸

Treatment options include aminoreduction of the recipient sac, amniotic membrane septostomy, and fetoscopic ablation of communicating vessels.^{109–111} Recently, endoscopic laser coagulation has become the treatment of choice for severe TTTS diagnosed before 26 weeks' gestation. In a multicenter European trial, twins with severe TTTS of all Quintero stages were randomized to undergo fetoscopic laser ablation or standard amnioreduction therapy. The trial was stopped after 142 women were randomized, because of the clear benefit of the laser approach. Endoscopic laser ablation led to improved outcomes in all variables examined, including increased fetal survival and decreased incidence of neurologic complications.¹⁰⁶

Congenital Heart Defects

Fetal intervention may play a role in the management of some fetuses with rare congenital heart defects, including those with severe aortic or pulmonary stenosis, and hypoplastic left heart syndrome with intact or highly restrictive atrial septum.^{112–114} There is evidence that fetuses with aortic or mitral valve stenosis may progress to hypoplastic left heart syndrome, presumably as a result of decreased ventricular filling. Furthermore, critical pulmonary stenosis or atresia with intact ventricular septum may progress to the so-called "hypoplastic right heart syndrome." Staged palliative surgery is the only therapeutic option for newborns with these conditions, and mortality remains significant. The goals of fetal intervention for these anomalies are to relieve the obstruction, restore normal cardiac physiology, and reverse the progression toward ventricular hypoplasia. In an initial report from investigators at Children's Hospital, Boston, in which 20 fetuses underwent balloon dilation of a stenotic aortic valve at 21 to 29 weeks' gestation, five fetuses died following the procedure.¹¹⁴ Of 14 who were thought to have a technically successful procedure, three had evidence of a two-ventricle heart postnatally, thus supporting the experimental rationale. More recently, Tworetzky reported the predictors of technical success and postnatal biventricular outcome after in utero aortic valvuloplasty in 70 fetuses. The technical success rate was 74%, and 17 had biventricular circulation postnatally.

The authors developed a multivariable threshold scoring system allowing highly sensitive and moderately specific identification of fetuses able to survive postnatally with a biventricular circulation.¹¹⁵ Tworetzky also reported the outcomes of in utero atrial septoplasty in fetuses with hypoplastic left heart syndrome. Of 21 procedures attempted, 19 were technically successful. Although the authors could not conclude that this particular procedure improved survival given the small patient size, they did find that creation of a defect greater than 3 mm was associated with better postnatal oxygenation and less frequent need for emergent postnatal intervention.¹¹² It is likely that a prospective randomized trial will be needed to prove the efficacy of fetal intervention for this disorder.

Fetal Intervention for Other Anomalies

Fetal intervention is indicated for a number of other fetal conditions, including amniotic band syndrome and twin reversed arterial perfusion (TRAP) sequence. Fetoscopic lysis of constricting amniotic bands may lead to limb salvage and improved outcome.^{116–118} Similarly, in the TRAP sequence, fetoscopic ligation or ablation of the acardiac twin's umbilical cord is the treatment of choice.¹¹⁹

FUTURE OF FETAL INTERVENTION

There will always be a role for fetal intervention in the treatment of certain specific congenital structural abnormalities. The exact nature of this role, however, is under constant reevaluation and change. The primary goal of fetal therapy is to improve the outcome of the affected fetus while minimizing maternal risks. If fetal outcomes can be improved by alternative means, such as lung liquid ventilation or other postnatal therapies that pose no risks to the mother, then indications for fetal therapy will decrease. On the other hand, as the risks and complications of fetal surgery continue to decrease, such as those related to preterm labor and chorioamniotic membrane separation, then the role for fetal interventions may increase. Increased miniaturization of fetoscopic equipment and optics, advances in robotics, newer approaches to closure of the uterus and fetal membranes, and advances in our understanding and treatment of preterm labor will enhance our ability to change the outlook for an increased number of fetuses with congenital malformations.

CHAPTER 105 ■ PEDIATRIC HEAD AND NECK

KEITH T. OLDHAM AND JOHN J. AIKEN

KEY POINTS

- 1 Airway obstruction is the most serious complication of neck masses in children, and in infants presents with restlessness, followed by tachypnea, dyspnea, chest-wall retractions, and respiratory arrest.
- 2 Infants are obligate nasal breathers; thus, congenital lesions that obstruct the nasal passages or nasopharynx (choanal atresia, encephalocele, teratoma) typically cause early respiratory distress.
- 3 Acute epiglottitis presents as a rapidly progressive illness with severe stridor, airway obstruction, drooling, and difficulty swallowing and with signs of systemic toxicity, including an elevated temperature and white blood cell count, tachypnea, and tachycardia.
- 4 Branchial cleft sinuses present as cutaneous openings and are most often noted in infancy or at an early age, whereas cysts typically appear later in childhood when they accumulate secretions; treatment is complete surgical removal.
- 5 Thyroglossal duct cysts or remnants arise when embryonic elements persist along the tract of descent of the thyroid gland; treatment requires complete removal of the cyst, its entire tract, and the central portion of the hyoid bone.

- 6 Benign cervical lymphadenopathy is the most common neck mass in childhood.
- 7 Lymphangiomas are masses of disorganized, dilated lymph channels that arise when communications with the

internal jugular system fail to develop in portions of the lymphatic channels; the larger lesions with macrocystic dilated lymphatic channels are often referred to as *cystic hygromas*.

Surgical lesions of the head and neck are common in infants and children and include a broad spectrum of congenital and acquired disorders. Most lesions of the head and neck in children are benign (80% to 90%) and the etiology is congenital or inflammatory, but occasionally neoplastic lesions are encountered. Congenital lesions include vascular malformations, hemangiomas, branchial cleft anomalies, thyroglossal duct cysts, dermoid and epidermoid cysts, and others. The most common inflammatory neck masses are lymph nodes, but it is not uncommon for congenital lesions to be unnoticed until they become infected and present as a neck abscess. Neck masses in children may present clinically as asymptomatic masses or as life-threatening emergencies due to airway obstruction.

Malignant lesions of the head and neck in children are rare and may be primary tumors or represent metastatic disease to neck lymph nodes. Malignant lymphoma is the most common primary malignancy of the head and neck region in children. Other malignant neck masses occasionally encountered include rhabdomyosarcoma, thyroid carcinoma, and neuroblastoma.

An understanding of the relevant embryology and developmental anatomy of head and neck structures is important to enable efficient assessment, workup, and management of these lesions. Early biopsy is essential if there is any question of malignancy. This chapter focuses on the general principles and management of airway obstruction in infants and children and the most common head and neck lesions seen in pediatric surgical practice.

IMAGING STUDIES

In most head and neck masses in infants and children, an understanding of the pertinent developmental anatomy and embryology allows for a diagnosis on physical examination and diagnostic imaging is not required. In atypical cases or if the diagnosis is in question, an ultrasound, computed tomography (CT) scan, magnetic resonance imaging (MRI) scan, or fine-needle aspiration (FNA) may be helpful.

With the advent of cross-sectional imaging, the traditional cervical triangle method of organizing the anatomy of the neck has been largely replaced by a system that defines neck spaces according to the cervical fascial planes. The cervical spaces of the suprahyoid and infrahyoid neck include the sublingual space, submandibular space, buccal space, parotid space, parapharyngeal space, carotid space, masticator space, pharyngeal mucosal space, visceral space, retropharyngeal space, posterior cervical space, and perivertebral space.

Ultrasound is particularly helpful in distinguishing cystic from solid masses and identifying the presence of fluid within a lesion, as within a maturing deep cervical abscess. In addition, Doppler ultrasound can evaluate the vascularity of the lesion. Ultrasound should be considered as the first-line investigation because it has advantages of being noninvasive, does not involve ionizing radiation, and does not require sedation.

CT scan and MRI are used selectively to provide more detailed anatomic information and delineate extensions of head and neck lesions into the thorax, axilla, or intracranial space. While both CT scan and MRI can provide detailed multiplanar images of anatomic landmarks and tumor extension, CT is better able to demonstrate invasiveness and bony destruction. MRI provides three-dimensional soft tissue detail and is particularly useful for spinal cord involvement or intracranial extension of neck masses, but has higher costs and frequently requires seda-

tion of younger patients. T2-weighted imaging identifies areas of increased vascularity, and T1-weighted images enhanced with gadolinium allow precise localization of central nervous system tumors. T1 can also delineate the position of the facial nerve with respect to a parotid tumor.

Gallium-67 scanning is useful in the initial staging and monitoring of disease response and recurrence in high-grade lymphomas. Positron emission tomography (PET) scanning is a functional imaging technique that maps the location and concentration of the intravenously injected radioactive glucose analogue 2-fluoro-2-deoxy-D-glucose (FDG) in metabolically active tumors. In contrast to CT and MRI, which are modalities primarily depicting anatomic details, PET provides information about metabolism. Neoplastic cells incorporate more of the glucose analogue and thus produce more-intense images than surrounding normal tissue.

Additional radiographic studies that may be needed to evaluate a neck mass include chest radiograph, bone scan, and CT scans of the abdomen, pelvis, chest, and brain as part of a metastatic workup if a malignant tumor is suspected or diagnosed. A chest radiograph can demonstrate pulmonary involvement in tuberculosis or a potentially systemic fungal disease.

AIRWAY OBSTRUCTION

Many lesions, both congenital and acquired, can produce airway obstruction in infants and children. They may be intrinsic or extrinsic to the airway and vary from clinically insignificant to universally fatal.¹

- 1 Airway obstruction is the most serious complication of neck masses in children. Often the first significant sign of respiratory distress in an infant is restlessness, followed by tachypnea, dyspnea, chest-wall retractions, and respiratory arrest if the obstruction is not relieved. It is crucial to establish an adequate airway and to administer respiratory support while proceeding with the diagnostic evaluation. Supportive interventions may include simple measures such as repositioning the infant, clearing or suctioning the nose and mouth, and administering supplemental oxygen, or more-extreme measures, such as endotracheal intubation or tracheostomy. Evaluation includes a careful history and physical examination, chest radiography, and arterial blood gas analysis. A nasogastric tube should be passed into the stomach, as gastric distention limits excursion of the diaphragm and can significantly contribute to respiratory compromise. Laryngoscopy and bronchoscopy are employed as needed.

- 2 Because infants are obligate nasal breathers, congenital lesions that obstruct the nasal passages or nasopharynx (choanal atresia, encephalocele, teratoma) typically cause early respiratory distress. These disorders are readily identified by physical examination and emergent management is usually placement of an oropharyngeal airway. Airway obstruction at the level of the oral cavity in newborn infants is often a consequence of macroglossia or structural abnormalities such as micrognathia. Macroglossia may be a consequence of muscular hyperplasia and hypertrophy, as in Beckwith-Wiedemann syndrome and congenital hypothyroidism, or of diffuse involvement of the tongue with tumor (hemangiopericytoma, lymphangioma, neurofibromatosis).² Structural abnormalities, such as Pierre-Robin syndrome (hypoplastic mandible with cleft palate), cause respiratory distress as the tongue falls posterior and obstructs the airway. Cysts or tumors of the pharynx or a mass arising at the base of the tongue, such as a lingual thyroid, may also obstruct the

airway.³ Clinically, upper airway obstruction, above the glottis or larynx, is characterized by dyspnea, tachypnea, and suprasternal, intercostal, and costal margin retractions, but the child has no significant difficulty exhaling, and the voice and cry are normal. Emergency management consists of placing an oropharyngeal airway. Placing the infant in a prone position allows the tongue to fall forward and often provides significant relief. The infant may be fed through an orogastric feeding tube pending definitive correction of the obstruction. In extreme cases, a tracheostomy may be necessary.

Laryngeal obstruction can result from congenital or acquired vocal cord paralysis or tumors or cysts originating in the neck. Hemangiomas, lymphatic malformations (cystic hygromas), and teratomas are the most common cervical tumors in infants and young children. Laryngoscopy may be required to differentiate these lesions. Emergency management of such malformations frequently requires placement of an endotracheal tube or tracheostomy. Endotracheal intubation can be difficult in the setting of a large neck mass, possibly causing displacement of the larynx, and bronchoscopy may be necessary with passage of the tube over a flexible bronchoscope. After the airway is stabilized, further diagnostic evaluation may include neck and chest radiography, CT, MRI, and laryngobronchoscopy. Tracheostomy may be necessary at the time of definitive surgical excision, and placement of a gastrostomy tube may also be indicated if feeding problems are anticipated. Hemangiomas are the most common tumors involving the larynx; they often respond to intralesional or systemic steroids, or may regress spontaneously.⁴

Acquired Obstruction

Foreign body aspiration and acute epiglottitis are common causes of acquired airway obstruction in children. Acute epiglottitis most commonly occurs in children 2 to 4 years of age, and *Haemophilus influenza* type B can be isolated in greater than 90% of cases. Since the introduction of *H. influenzae* vaccine in 1991, the incidence of this illness has been reduced in children.⁵ Pneumococci and β -hemolytic streptococci are also causative organisms in epiglottitis. Acute epiglottitis typically presents as a rapidly progressive illness with symptoms of severe stridor, airway obstruction, drooling, and difficulty swallowing and with signs of systemic toxicity, including an elevated temperature and white blood cell count, tachypnea, and tachycardia. Prolonged inspiratory stridor that worsens in the supine position is characteristic. In advanced cases, the child usually sits erect and leans forward, is anxious, drools, and becomes increasingly exhausted with air hunger. Attempts to examine or visualize the larynx may result in sudden airway occlusion with aspiration and respiratory arrest and therefore should be performed only in the operating room with personnel prepared to perform endotracheal intubation or tracheostomy. If the child's condition permits, lateral neck radiographs with soft tissue techniques are obtained and should confirm the diagnosis by demonstrating edema of the epiglottis and ballooning of the hypopharynx.

The most important aspect of management is establishing a definitive diagnosis without delay. Once the diagnosis is established, maintaining an adequate airway is vital. Because of the high risk for progressive airway obstruction, standard therapy often involves short-term endotracheal intubation performed in the operating room under general anesthesia. The surgeon should be prepared to perform a tracheostomy in the event that the airway cannot be secured with an endotracheal tube or flexible bronchoscope. The inflammatory process typically resolves rapidly with administration of intravenous antibiotics, and intubation is seldom required beyond 3 days. Ampicillin is no longer recommended because of the high incidence of resistant *Haemophilus*. The drug of choice is usually a third-generation cephalosporin, such as cefoxitin or cefuroxime. The timing of extubation should be determined by resolution of clinical signs and symptoms and direct visualization of the supraglottic area

by fiberoptic nasopharyngoscopy. In the past, tracheostomy was the standard therapy, but comparative reviews demonstrate that short-term endotracheal intubation is associated with less morbidity and fewer complications.⁶

BRANCHIAL CLEFT REMNANTS

Remnants of the embryonic branchial apparatus (cysts, sinuses, fistulas, and cartilaginous rests) are common in children. Although congenital by definition, they are often unrecognized or misdiagnosed until symptoms or complications initiate an evaluation. Sinuses, fistulas, and cartilaginous remnants are usually apparent at birth and noticed early in life, whereas cysts are more likely to present later in childhood as a neck mass when they fill with secretions. All of these lesions have a risk of infection and can present as an abscess or with drainage and surrounding erythema. Rarely, these remnants may harbor malignancy.⁷

Anatomy and Embryology

During the fourth to eighth week after fertilization, four pairs of well-developed ridges (branchial arches) and associated clefts are prominent in the lateral cervicofacial region of the human embryo. Each consists of a cartilaginous center (mesoderm), an intervening cleft (ectoderm), an internal pouch (endoderm), and a parent nerve. The mature structures of the head and neck are derivatives of these paired branchial arches, clefts, and pouches in the embryo.⁸ The contributions of the branchial arches and clefts to the structures of the neck and jaw are summarized in Figure 105.1. Incomplete closure or resorption of these primordial elements, particularly clefts, may result in development of cysts, sinuses, fistulas, and masses.

The first branchial arch forms the mandible and the maxillary process of the upper jaw. The dorsal portion of the first branchial cleft remains open as the external auditory canal; the other external clefts are obliterated. The closing plate between the first pouch and cleft becomes the tympanic membrane. The first pouch becomes the eustachian tube, the middle-ear cavity,

FIGURE 105.1. Derivation of various areas of the head and neck from the branchial arches and clefts of the embryo.

and the mastoid air cells. Abnormal development of the first branchial arch results in a host of facial deformities including cleft lip and palate, abnormal shape and contour of the external ear, and malformation of the internal ossicles. The second branchial arch and its internal pouch form the hyoid bone and the cleft of the tonsillar fossa. The palatine tonsil and the supra-tonsillar fossa are also remnants of the second branchial pouch.

Remnants of the first branchial cleft are found along the base of an imaginary fold extending from the auditory canal behind and below the angle of the mandible to just below the midpoint of the mandible. The critical anatomic relationship for first branchial cleft remnants is their intimate association to the facial nerve and its proximal branches.

Second branchial cleft remnants are found along any part of a line extending from the tonsillar fossa inferiorly to a point on the lower third of the anterior border of the sternocleidomastoid muscle. The third cleft migrates low in the neck to form the inferior parathyroid glands and the thymus. The fourth cleft also migrates but stops higher up in the neck and forms the superior parathyroid glands and C cells of the thyroid gland.

Clinical Aspects

4 All abnormal branchial remnants are congenital abnormalities and therefore are present at birth. Branchial cleft sinuses present as cutaneous openings and are most often noted in infancy or at an early age, whereas cysts typically appear later in childhood when they accumulate secretions. Branchial cleft sinuses and fistulas frequently produce mucoid drainage from the skin opening, and the cutaneous openings are occasionally marked by skin tags or subcutaneous cartilaginous remnants. The tract is often palpable.

First branchial cleft remnants present as a sinus opening near the angle of the mandible in the region of the submandibular triangle or preauricular region. These sinus tracts extend from their submandibular opening superficial to the mandible up to the external auditory canal. The tract is intimately associated with the superficial lobe of the parotid gland and facial nerve.⁹ First branchial anomalies are less common than those of the second cleft and are often misdiagnosed. A history of recurrent infection, often leading to incision and drainage, is generally present. A key to the diagnosis is a history of nonpurulent drainage before infection.

Second branchial anomalies are six times more common than first branchial anomalies and present as an opening along the anterior border of the sternocleidomastoid muscle in its lower third and may be bilateral (10% of cases) (Figs. 105.2 and 105.3). The sinus tract of a second branchial anomaly passes through the subcutaneous tissues beneath the platysma muscle, over the bifurcation of the carotid artery, and between the external and internal carotid arteries, and enters the lateral wall of the pharynx at the tonsillar fossa. The tract may be complete (fistula) or incomplete (sinus).

Cysts or infections arising from the third and fourth branchial arch and cleft are rare and much more challenging to diagnose and treat than first and second branchial remnants.¹⁰⁻¹² For both third and fourth remnants, the internal opening is located in the piriform sinus (Fig. 105.4). Radiographic imaging is typically not necessary for first and second branchial anomalies, but barium studies and CT may be useful in demonstrating a piriform sinus fistula. The third branchial cleft sinus presents as a mass lower in the neck than the second branchial sinus. Its course is superior and posterior to the carotid sheath, most commonly on the left side (90%). Third and fourth branchial anomalies generally present before age 10 years, often as a left thyroid abscess. Contrast esophagram may demonstrate the fistula between the piriform sinus and the neck.^{13,14} Because of the risk of the development of infection in any of the branchial cleft anomalies, excision is recommended at diagnosis of a noninfected lesion. Surgery in infants may be delayed until age 3 to 6 months.

FIGURE 105.2. Areas of the neck in which cysts and sinuses originating from the first and second branchial clefts are usually found.

Treatment and Outcome

The goal of treatment of any branchial cleft remnant is complete surgical excision. The operation is usually performed once the diagnosis is secure, provided no active inflammation or infection is present. If infection is found, antibiotics are administered initially, and the operation is delayed several weeks to allow the inflammation to resolve. This approach provides the best opportunity for complete excision of the tract. Abscesses are managed initially with limited incision and drainage to control infection. Formal excision of branchial cleft lesions in the presence of active inflammation or infection is associated with a higher recurrence rate secondary to incomplete excision¹⁵ and an increased likelihood of injury to nerves (facial, hypoglossal) and other vital structures. Important principles for neck dissection for excision of branchial cleft remnants include avoidance of muscle relaxants, selective use of a nerve stimulator, and cautious use of retractors and electrocautery.

The operation is performed under general anesthesia. The patient is positioned with the head and neck slightly extended. A small elliptical incision along the Langer lines incorporates

FIGURE 105.3. Branchial cyst. Most of these cysts arise from the second branchial cleft and occur laterally in the neck. The cysts have a thin wall, contain turbid fluid, and are lined by stratified squamous or respiratory-type epithelium. (From Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999, with permission.)

FIGURE 105.4. Types of first, second, and third branchial cleft remnants. Sinuses and fistulas are seen most often in infants and young children, whereas cysts usually appear at a later age.

the sinus opening, excising the ellipse of skin without dividing the attachment to the sinus tract. The tract is identified and dissection continues cephalad immediately along the tract to avoid injury to contiguous structures. The dissection for a second branchial remnant penetrates the platysma muscle and cervical fascia, ascends along the carotid sheath to the level of the hyoid bone, turns medially between the branches of the carotid artery, and courses behind the posterior belly of the digastric muscle and stylohyoid muscle and in front of the hypoglossal nerve before ending in the pharynx, most often in the tonsillar fossa. A finger in the mouth pressing downward gently in the tonsillar fossa helps identify the endpoint of the dissection, where the tract is suture ligated with absorbable suture and divided (Fig. 105.5). Occasionally, in older patients with a long tract, a second, “stepladder” incision may be required to complete the dissection.

The tract for a first branchial cleft remnant typically courses from its sinus opening along the angle of the mandible cephalad in proximity to the parotid gland and facial nerve and ends at the external auditory canal (Fig. 105.6).¹⁶ Draping should allow visualization of the lateral aspect of the eye and corner of the mouth. A nerve stimulator for electrophysiologic localization may be helpful to avoid injury to the main trunk of the facial nerve or its proximal branches. The superficial lobe of the parotid gland may need to be reflected upward to expose the tract or may require excision in cases of chronic infection.

For third and fourth branchial remnants, the dissection follows the tract to its termination in the piriform sinus. Endoscopy at the start of the operation may enable cannulation of the tract from above with a Fogarty catheter or small feeding tube, which greatly facilitates localization of the tract during excision.¹⁴ Third or fourth branchial remnants almost all occur on the left side (90%). The thyroid gland is exposed through a standard collar incision, and the appropriate lobe is mobilized. The recurrent and superior laryngeal nerves and parathyroid glands should be identified and protected. If no discrete cyst or tract is found, the fistula may be located at the laryngeal level near the cricothyroid membrane. This is an anatomic area where the recurrent laryngeal nerve is particularly at risk for injury. The fibers of the inferior constrictor

muscle are bluntly spread to expose the piriform recess. Extreme caution should be exercised in this region to preserve the external branch of the superior laryngeal nerve. The tract typically passes inferior and external to the recurrent laryngeal nerve along the trachea to the superior pole of the thyroid gland. It may end blindly near the gland or penetrate the capsule to terminate in the parenchyma of the left thyroid lobe. Thyroid lobectomy or resection of the superior pole is carried out as indicated by the extent of the cyst (Fig. 105.7).¹⁷ Once surgical extirpation is complete, the wound is closed in layers with absorbable suture. Drainage is only used if infection is encountered during the dissection. Recurrence is rare (<5%) and implies that the entire epithelium-lined tract was not excised.

When remnants of the branchial apparatus persist as cartilaginous rests, these masses are generally small and present subcutaneously along the anterior border of the sternocleidomastoid muscle. The lesion is typically visible and palpable on physical examination and may be bilateral (10% of cases). An accompanying sinus or cyst is uncommon and infection is rare. Excision is for cosmetic reasons.

Preauricular cysts and sinuses are also common in infants and children. They are believed to arise as a result of anomalies in the formation of the external ear and represent vestiges of the first two branchial arches. These pits are lined with squamous epithelium and may contain hair and other skin appendages. They differ from first branchial cleft cysts in that they are more common, often bilateral, often inherited, and only rarely are complicated by infection, involvement of the facial nerve, or entrance into the external auditory canal.¹⁸ They extend from the skin surface down through the subcutaneous tissue in close proximity to the superficial temporal artery and typically terminate in the cartilage of the external auditory canal. Operative excision is recommended to avoid infection. Draining sinuses and infected cysts require antibiotic treatment, incision and drainage for failure to resolve, and delayed excision to prevent recurrence. Complete surgical excision of the sinus tract and cyst to the level of the temporalis fascia is the treatment of choice in the uninfected draining sinus. The cyst or sinus may have multiple branches, making complete resection difficult, and some clinicians have advocated an extended incision and

FIGURE 105.5. A: Single incision in the lower part of the neck with the sinus tract developed to usual length. B: The anesthesiologist's finger depresses the tonsillar fossa to facilitate complete dissection of the sinus tract through the single incision.

removal of a small portion of adjacent cartilage to reduce the risk of missing one of these branching tracts.^{19,20}

THYROGLOSSAL DUCT CYST

Thyroglossal duct cysts are the most common neck mass in children. Most thyroglossal duct cysts are diagnosed in early childhood. The gender incidence is approximately equal, in contrast to thyroid disorders, in which girls are predominantly affected. Rare cases of familial inheritance with an autosomal dominant distribution have been described.

FIGURE 105.6. Relations of cyst or sinus of the first branchial cleft. Note especially the proximity to the facial nerve and external auditory canal.

Anatomy and Embryology

- 5** Thyroglossal duct cysts arise when embryonic elements persist along the tract of descent of the developing thyroid gland. The thyroid gland starts as a diverticulum at the foramen cecum at the base of the tongue and descends in the sixth

FIGURE 105.7. Relations of a third or fourth branchial cleft cyst or sinus to the thyroid gland and piriform sinus.

FIGURE 105.8. Locations of thyroglossal duct cysts.

week of fetal life to its pretracheal position in the neck. In its descent, the tract most often passes through the central portion of the hyoid bone, but it may pass in front or behind the hyoid. The normal thyroglossal duct involutes by the eighth fetal week. Remnants of a portion of the duct may lead to cyst formation or ectopic thyroid tissue anywhere along the tract (Fig. 105.8). Complete failure of descent leads to a lingual thyroid, with the thyroid developing beneath the foramen cecum within the tongue itself or just beneath it. Ectopic thyroid tissue is identified within the thyroglossal duct remnant in approximately 25% to 35% of cases, and papillary adenocarcinoma has been described in up to 10% of patients undergoing thyroglossal duct cyst excision in adulthood.^{11,21,22}

Clinical Aspects

Thyroglossal duct cysts are present at birth but rarely present clinically in infancy. The most common presentation is a midline cystic neck mass (Fig. 105.9) or draining sinus in early childhood, most by age 5 years.^{23,24} Infection and abscess formation frequently arise because of communication with the mouth and contamination by oral flora. If it is not infected, the cyst is usually apparent by palpation. The cyst is at or near the midline, most commonly overlying the hyoid bone, but may be found at any level from the submental region to the upper trachea.¹⁵ It is typically smooth, soft, and nontender in the absence of infection. Because the cyst and tract are attached to the foramen cecum of the tongue, the cyst often moves with protrusion of the tongue and swallowing. In contrast to branchial cleft remnants, a thyroglossal duct cyst does not have a sinus opening to the skin unless infection has resulted in spontaneous drainage or an incomplete excision or incision and drainage procedure has previously been performed. The cyst and duct are lined with stratified squamous or pseudostratified columnar epithelium with mucus-secreting glands. Ectopic thyroid tissue may be present in the cyst or tract, and in rare cases this may represent the child's only thyroid tissue. Preoperative thyroid scans with radioactive isotopes have been employed by some, but usually one can be reassured by simple palpation of the thyroid gland in its normal pretracheal location. Furthermore, even in the exceptional cases in which the thyroid tissue in the cyst is the only

FIGURE 105.9. A thyroglossal duct cyst.

functional thyroid tissue, excision of the cyst is still mandated because of the risk for infection and the malignant potential of the dysgenetic thyroid tissue.²⁵ Review of the pathologic specimen after excision is important. If thyroid tissue is present in the specimen, thyroid function tests should then be performed and thyroid replacement therapy prescribed as indicated. As with branchial cleft remnants, definitive excision should not be performed in the presence of infection or inflammation because of the increased risk for incomplete excision and injury to contiguous structures. Preoperative preparation may require incision and drainage or a period of antibiotics.

Treatment

Successful management requires complete removal of the cyst, its entire tract, and the central portion of the hyoid bone. In 1920, Sistrunk²⁶ not only described the importance of removing the central portion of the hyoid bone but also emphasized the possible existence of multiple tracts and therefore the importance of an en bloc dissection and removal of a core of tissue to the base of the tongue. Before these operative principles were elucidated, most series reported a recurrence rate of 20% or higher. The operation is performed under general endotracheal anesthesia. The patient's neck is extended, and often a roll is placed beneath the shoulders. A transverse skin incision is made directly over the cyst, usually in the infrahyoid region. If a sinus opening exists to the skin from prior infection or surgery, an elliptical incision to include the sinus is used. The cyst is easily identified beneath the platysma muscle. Dissection adjacent to the cyst wall mobilizes the cyst, and the tract is identified. Dissection is continued cephalad up to the hyoid bone. The muscular attachments to the superior and inferior portions of the body of the hyoid bone are divided, and the central portion of the hyoid bone is removed in continuity with the cyst and tract. Beyond the hyoid bone, a core of tissue 5 to 10 mm

in diameter is excised through the muscles of the base of the tongue to the foramen cecum, where the tract is suture ligated with absorbable suture.^{27,28} Identification of the endpoint of the dissection at the foramen cecum may be facilitated by having the anesthesiologist place downward pressure on the base of the tongue with a gloved finger. The ends of the hyoid bone are not reapproximated. The wound is copiously irrigated and closed in layers. A drain may be used, particularly if the patient has a history of infection, but most often it is not required. Complete excision of a thyroglossal duct cyst is generally curative. Contemporary recurrence rates generally are less than 10% and usually related to prior infection or incomplete surgical excision. Thyroid neoplasia (<1%) has been described in ectopic thyroid tissue, both associated and unassociated with thyroglossal duct cysts.^{11,21,22}

Other midline neck masses that occur in children include dermoid and epidermoid inclusion cysts, pathologic lymph nodes, cervical thymic cysts, and bronchogenic cysts. Dermoid and epidermoid cysts consist of ectodermal elements that were sequestered beneath the skin or failed to separate from the neural tube.^{29,30} Dermoids are distinguished histologically from epidermoids by the accessory glandular structures they possess, including sebaceous glands, hair follicles, connective tissues, and papillae. The most common location of dermoids in infants and children is the lateral orbital ridge. They are usually soft, mobile, and nontender, and typically demonstrate slow growth along with the child's linear growth, becoming clinically apparent in early childhood.

Midline dermoid cysts probably represent entrapment of epithelium of branchial arch origin at the time of embryologic midline fusion.^{31,32} Differentiation from thyroglossal duct cysts can usually be accomplished on physical examination, with dermoid cysts typically smaller and more superficial and that do not move with protrusion of the tongue. Midline dermoid cysts overlying the nasal bridge occasionally penetrate the bone, forming a dumbbell-shaped mass with dermoid elements on either side of the bone. CT imaging and occasionally MRI should be performed for midline facial dermoid cysts or fixed or atypical lesions in other locations to exclude intracranial extension. Complete surgical excision is the treatment of choice for all dermoid and epidermoid cysts to confirm the diagnosis, to prevent rupture or infection, and for cosmetic reasons. This is generally performed as an open operation, although increasing experience is accruing using endoscopic minimally invasive techniques.³³ Although exceedingly rare, malignant degeneration has been reported.

LYMPHADENOPATHY

- 6 Benign cervical lymphadenopathy is the most common neck mass in childhood.³⁴ Cervical nodes up to 1 cm in diameter are normal in children younger than 12 years of age, and many children in all age groups have palpable lymph nodes that are not associated with infection or systemic illness. The anterior cervical, occipital, retroauricular, and submandibular nodal groups are the ones most often enlarged. Bacterial and viral infections, particularly upper respiratory tract infections, otitis media, and pharyngitis, are the most common cause, with bacterial infections most likely to progress to acute suppurative lymphadenitis. Unilateral nodal enlargement is usually the result of pyogenic infection originating in the tonsils and oropharynx, while bilateral disease is frequently observed in viral upper respiratory tract infections.

Fungal infections are an uncommon cause of lymphadenopathy in children with the exception of immunocompromised patients. Other important inflammatory causes of cervical lymphadenopathy include cat scratch disease, mononucleosis, atypical mycobacteria (AMB) infections, and tuberculosis. Enlarged cervical or supraclavicular lymph nodes may also be the present-

ing manifestation of certain malignancies, both primary and metastatic, particularly lymphoma.³⁵ Rare noninfectious causes of cervical lymphadenopathy include Kawasaki disease, sarcoidosis, sinus histiocytosis (Rosai-Dorfman syndrome), and histiocytosis X.

Acute suppurative cervical lymphadenitis most frequently occurs in young children, between 6 months and 3 years of age. Typically, enlargement of the lymph node is preceded by an episode of pharyngitis or an upper respiratory tract infection. The most common causative organisms are penicillin-resistant *Staphylococcus aureus* and group A β -hemolytic streptococci.³⁶ Bacterial lymphadenitis is often characterized by rapid nodal enlargement. The enlarged node initially becomes erythematous and tender, with surrounding cellulitis. Systemic signs of infection are usually present—fever, tachycardia, and elevated white blood cell count with a leftward shift. Fluctuance develops as the abscess forms. Management includes systemic antibiotics to cover *Streptococcus* and *Staphylococcus* organisms. Occasionally, aspiration of the purulent and necrotic material with a large-bore needle provides fluid for culture, and in combination with antibiotics, may effect resolution without formal incision and drainage. More frequently, fluctuant nodes require incision and drainage, with the use of either conscious sedation and local anesthesia, or general anesthesia in the operating room. The most important consideration when performing incision and drainage of a fluctuant neck mass is control of the airway. A skin-line incision is made over the area of maximal fluctuance and the abscess cavity is drained, with care to disrupt any loculations. The incision should be designed with concern for complete drainage; avoidance of vital structures, particularly the branches of the facial nerve; and cosmesis. Incisions high or low in the neck should be made in parallel with the angle of the mandible or clavicle and at least 1 cm away from these structures to avoid hypertrophic scar formation. The wound is loosely packed open and covered with a dry gauze dressing. Drains may be used in cases of deep or complex neck abscesses, but are not generally necessary in uncomplicated cases. Recurrence is rare and should prompt evaluation for an underlying immunodeficiency or congenital anomaly. Viral infections are also associated with the development of acute cervical lymphadenitis, which is typically bilateral, rarely suppurative, and generally self-limited with spontaneous resolution.

Lymphadenitis is chronic or subacute when enlargement of lymph nodes persists long after any evidence of infection has disappeared or the patient has no history or evidence of a precipitating infectious illness. The child may have a history of frequent upper respiratory infections, otitis media, tonsillitis, sinusitis, or allergic rhinitis or eczema. Systemic signs of infection are not present. The nodes are usually solitary, nontender, mobile, and soft. Enlarged nodes that are asymptomatic, less than 1 cm in diameter, and soft and that have been present for less than 8 weeks do not require treatment. Excisional biopsy should be performed for any lymph node that is larger than 2 cm in diameter, persists beyond 8 weeks, or demonstrates worrisome characteristics such as firmness, immobility, or rapid growth. Communication between the surgeon and pathologist is important to ensure that complete culture data is obtained, including cultures for tuberculosis, atypical mycobacterial infection, and cat scratch disease, as well as histopathologic and flow cytometry studies for possible malignancy. Most of the lymph nodes that come to biopsy are benign and the histologic examination reveals “reactive hyperplasia.”

Mycobacterial lymphadenitis and cat scratch disease also commonly cause lymphadenopathy in children.³⁷ Mycobacterial lymphadenitis is usually caused by atypical mycobacteria of the *Mycobacterium avium-intracellulare-scrofulaceum* (MAIS) complex.^{38–40} Pathogens typically enter the body through breaks in the mucus membranes of the oropharynx during the eruption of teeth. Unlike *Mycobacterium tuberculosis*, person-to-person transmission of MAIS has not been demonstrated.

Infection with *M. tuberculosis* is uncommon in children in the United States, and when present, it is usually accompanied by positive findings on chest radiographs because the lung is the site of entry for this organism.

Atypical mycobacterial lymphadenitis occurs predominantly in children 1 to 5 years of age and is rare after the age of 12. The lymphadenopathy observed with AMB infection is typically asymptomatic with enlarged but nontender nodes and no associated fever or leukocytosis. The nodes are initially rubbery and firm, and submandibular or preauricular areas are most common. They later become matted together to form a confluent mass. If no treatment is given, drainage and sinus formation may occur spontaneously.

The child with tuberculosis scrofula is typically symptomatic with pulmonary tuberculosis. The results of chest radiography and skin testing with purified protein derivative standard are usually positive. For *M. tuberculosis* infection, a trial of antituberculosis chemotherapy is recommended. Current treatment regimens consist of multiple-agent chemotherapy with isoniazid and rifampin for 9 to 12 months and a third drug (pyrazinamide, streptomycin, or ethambutol) for the first 2 months.⁴¹

Atypical mycobacterial infections generally respond poorly to chemotherapy. When a lymph node biopsy is planned, if tuberculosis or atypical mycobacterial infection is suspected, complete excision is required. Incision and drainage or incomplete nodal excision in cases of atypical mycobacterial infection invariably leads to recurrence or cutaneous draining sinuses. Complete excision is generally curative, although there may be a role for adjunctive antimicrobial therapy with clarithromycin and rifabutin.⁴²

Cat scratch disease is a common cause of lymphadenitis in children in Western countries.⁴³ In most cases, the history reveals direct contact with a cat with the development of tender regional lymphadenopathy within 2 weeks of inoculation. Other animals, such as dogs and monkeys, have also been implicated in transmission. The site of inoculation is most commonly an extremity, resulting in inguinal, epitrochlear, or axillary adenopathy; however, cervical nodes are involved in as many as 25% of cases.^{44,45} The disease is believed to be caused by a gram-negative bacillus, *Bartonella henselae*, and typically begins as a superficial infection at the inoculation site on a limb. The diagnosis can be confirmed by several methods, including skin test antigen, *B. henselae*-based serologic indirect fluorescent antibody test, and enzyme immunoassays. The clinical presentation usually is lymphadenopathy with only mild tenderness and without systemic symptoms; however, severe complications including encephalitis, follicular conjunctivitis, and neuroenteritis can occur. No treatment is necessary if the diagnosis is secure (positive skin test result) because the illness is generally self-limited and lymphadenopathy resolves in most cases in 6 to 8 weeks without specific treatment. Antibiotics are not generally effective despite in vitro sensitivities. If the diagnosis is in doubt, complete excision is recommended and curative.

Although most lymphadenopathy in children is benign, malignant conditions such as Hodgkin disease and non-Hodgkin lymphoma are also common in children and frequently present as primary neck lymphadenopathy. Any case of a neck mass that has concerning examination characteristics, or that persists despite appropriate antibiotic therapy, requires FNA for cytology and likely excisional biopsy for definitive diagnosis.

rapidly, regress slowly, and never recur. Hemangiomas can occur anywhere in the body and the craniofacial region is common with frequent involvement of the tongue, subglottic area, and parotid glands. Single lesions predominate, but there also can be multiple lesions in up to 20% of infants, with the head, neck, and trunk being the areas most often affected. A superficial hemangioma is a well-demarcated, elevated, bright red mass or plaque that blanches incompletely with pressure. Sometimes a hemangioma can have a deep component that is a soft, flesh-colored, rubbery, ill-defined subcutaneous mass with a bluish hue. Risk factors for the development of infantile hemangiomas include female sex, Caucasian race, preterm birth, and low birth weight. Most hemangiomas are not clinically evident at birth but become apparent in the first few months of life, and 90% are evident by age 6 months.

Hemangiomas can be extensive and typically have a red or blue coloration and a spongy or rubbery texture on palpation. The presenting symptom for subglottic hemangioma is often stridor that is not present at birth but presents at age 1 to 3 months. Parotid hemangioma typically presents as an enlarging soft tissue mass in the parotid gland in the first 1 to 3 months of infancy. Cutaneous capillary hemangiomas may be present on the face, neck, or chest. Evaluation by ultrasonography with Doppler flow studies is usually diagnostic.⁴⁶ The natural history of these lesions is for significant growth (proliferative phase) in the first 6 to 12 months of life, followed by a period of minimal growth, after which involution and spontaneous resolution occurs by thrombosis and epithelialization.⁴⁷ If involution takes place, it is complete by age 5 years in 80% of patients. Biopsy of these lesions was recommended in the past but is no longer routinely performed in most centers. CT with intravenous contrast and magnetic resonance angiographic imaging are very useful in selected cases for evaluating the extent of tissue involvement. Angiography is invasive and rarely necessary for diagnostic purposes, but may be useful for treatment of large lesions by embolization. Biopsy remains important when the diagnosis is in question, particularly to rule out kaposiform hemangioendothelioma (KHE), a vascular tumor associated with profound thrombocytopenia.

Although most hemangiomas spontaneously resolve, up to 24% of infants will have complications, such as hemorrhage, ulceration, infection, and necrosis. Rarely (3% to 5%), hemangiomas may become quite large, involve vital organs, or produce life-threatening complications including hemorrhage, thrombocytopenia, and coagulopathy owing to platelet trapping, airway obstruction, or congestive heart failure. Periorbital hemangiomas should be recognized as particularly problematic with potential to lead to the development of astigmatism, ptosis, strabismus, amblyopia, and blindness.

Treatment of hemangiomas is challenging given the wide spectrum of disease, unpredictable biologic behavior, and natural tendency for involution. Most hemangiomas will follow the natural history of rapid growth followed by gradual spontaneous involution, and observation is appropriate. Aggressive treatment is necessary for infants at highest risk of complications. Lesions that, because of their location or growth, are obstructing the airway, involving the eye, or causing tissue destruction are generally treated with oral corticosteroids due to their antiproliferative effect (Fig. 105.10). The response is typically excellent. Other treatment options include topical and intralesional corticosteroids, pulsed-dye laser therapy, and surgical excision.

VASCULAR MALFORMATIONS

Hemangioma

Hemangiomas are endothelial tumors characterized by an increased proliferation and turnover of endothelial cells, and this differentiates them from other vascular malformations. Hemangiomas display a unique biologic behavior—they grow

LYMPHATIC MALFORMATIONS

Anatomy and Embryology

At about the sixth week of gestation, a system of clefts develops in the cervical mesenchyme that subsequently forms lymph channels. These channels give rise to jugular lymph sacs that become the cervical lymph nodes and lymphatics, ultimately

FIGURE 105.10. Capillary hemangioma. **A:** The lesion of the upper lid is large enough to partially occlude the visual axis and induced a significant astigmatic error and strong visual preference for the left eye, requiring occlusion therapy. Because it is located in the deeper tissue layers, this hemangioma appears more bluish than more superficially located lesions. **B:** Three days after intralesional steroid injection, the hemangioma has shrunk out of the visual axis. (From Tasman W, Jaeger E. *The Wills Eye Hospital Atlas of Clinical Ophthalmology*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001, with permission.)

draining into the internal jugular venous system (Fig. 105.11). **7** Lymphatic malformations are benign masses of disorganized dilated lymph channels that arise when portions of these primitive embryonic lymph sacs fail to develop communications with the internal jugular venous system. Although sequestered from the normal lymphatic channels, these sequestered lymph channels are lined by endothelial cells and continue to produce lymph fluid. In contrast to hemangiomas, the proliferative rate of the lining endothelial cells is normal. Lymphatic malformations can vary in size from a few centimeters in diameter to massive tumorlike lesions extending into the mediastinum. Radiologically and histologically, they are characterized as microcystic, macrocystic, or combined.

Lymphatic malformations tend to develop in close proximity to large veins and lymphatic ducts. Large macrocystic lesions are commonly found in the lateral cervical and submandibular region and are often termed *cystic hygromas*. Lesions that involve the tongue or extend into the mediastinum may result in stridor, cyanosis, apnea, or dysphagia with failure to thrive. Other locations for lymphatic malfor-

FIGURE 105.11. Lymphatic system in an 8-week-old human embryo. Development of the major and minor lymphatic sacs is well under way. The jugular lymphatic sac in the neck is prominent. Sequestration of tissue from any of the developing lymphatic structures leads to formation of a lymphangioma or cystic hygroma.

mations are the axilla/chest, extremities, retroperitoneum, and perineum. Most lymphatic malformations are evident early in life, with 65% present at birth, 80% evident within the first year of life, and 90% diagnosed by the age of 2 years.⁴⁸ They are more common (2:1) on the left side of the neck, presumably because the thoracic duct enters the subclavian vein on the left side. The physical examination characteristics of a soft, discrete, cystic, multiloculated mass are often sufficient for a definitive diagnosis. Spontaneous resolution is rare. Hemorrhage can occur within the lesion and is often the reason for the rapid enlargement sometimes noted clinically. When this occurs there is sudden swelling and ecchymosis. Intralesional bleeding is a predisposing factor for infection, and antibiotics should be initiated (Fig. 105.12).

Cellulitis is common in lymphatic malformations, particularly those in the head, neck, and perineum. This also commonly results in rapid expansion of the lesion with erythema, fever, and tenderness. In the newborn, large neck lesions may cause significant airway compromise or esophageal and pharyngeal obstruction. Symptoms such as pain or discomfort are rare unless the lesion has hemorrhaged or become infected. Approximately 10% of cervical lymphatic malformations extend into the chest.

Lymphatic malformations can be detected by prenatal ultrasonography, most often as septated or nonseptated lesions in the nuchal region. When associated with fetal hydrops, chromosomal abnormalities, or structural anomalies, early fetal death frequently is noted by 22 weeks' gestation. Lymphatic malformations demonstrated after parturition generally have a favorable prognosis. The physical examination findings of a soft, cystic, multiloculated mass are often sufficient for a definitive diagnosis. Ultrasonography, particularly with Doppler flow studies, is often useful to confirm the diagnosis. CT with intravenous contrast or magnetic resonance angiography is used selectively to evaluate extension of the lesion from one body space to another and delineate associated vital structures when planning for resection.

FIGURE 105.12. Infected cystic hygroma of the tongue. (From Fleisher GR, Ludwig W, Baskin MN. *Atlas of Pediatric Emergency Medicine*. Philadelphia, PA: Lippincott Williams & Wilkins; 2004, with permission.)

Treatment

Complete surgical excision is the optimal treatment for lymphatic malformations, but the tendency for these benign malformations to insinuate in and around vital structures can make complete resection difficult. With incomplete excision, disease recurrence is high (10% to 15%). Radical extirpative resections resulting in loss of function or severe deformity are not indicated. Spontaneous regression of these lesions is unusual but may occur after acute inflammation. Only two thirds of lymphatic malformations will be amenable to complete excision and one third will require partial excision or in the case of extensive or complex lesions staged excision due to involvement of vital structures within the lesion. Percutaneous aspiration usually is followed by prompt recurrence and may result in hemorrhage or infection and is not recommended except to emergently decompress a cyst and relieve airway obstruction. Radiation treatment has not been of benefit in the treatment of lymphatic malformations and has significant morbidity in the growing child. Injection of sclerosing agents, most commonly bleomycin, has been used but has significant potential complications of infection, gastrointestinal problems, and pulmonary fibrosis.⁴⁹ More recently, large cystic lesions in locations difficult to manage surgically have been treated by injection of OK-432, a monoclonal antibody produced by incubation and interaction of *Streptococcus pyogenes* with penicillin.⁵⁰ At present this treatment remains experimental but has demonstrated success in some difficult cases.

CHAPTER 106 ■ THE PEDIATRIC CHEST

TONY CAPIZZANI, RONALD B. HIRSCHL, AND ROBERT E. CILLEY

KEY POINTS

- 1 Pectus excavatum results from abnormal regulation of the growth of the costal cartilages with a corresponding posterior curve in the body of the sternum beginning at the manubrium and extending to the xiphoid; the deformity is rarely precisely symmetric, with one side (usually the right) slightly more curved in than the other.
- 2 Pectus excavatum repair should occur in late childhood or adolescence and is now most frequently performed with a rigid transversely oriented bar (Lorenz bar) that pushes the deformity back into place.
- 3 Pectus carinatum occurs less frequently than pectus excavatum and does not cause physiologic impairment; for operative repair, osteotomies and sternal fracture are performed in such a way as to depress the sternum.
- 4 Pulmonary sequestrations (PS) are abnormal lung tissue with anomalous systemic blood supply that can be either intralobar or extralobar lesions based on their relationship with the investing visceral pleura and adjacent normal lung tissue. They do not communicate normally with the trachea or a bronchus.
- 5 Congenital cystic adenomatoid malformations (CCAMs) have a normal vascular supply and communicate with the normal tracheobronchial tree. They result from excessive proliferation of bronchial structures without the development of the corresponding alveoli.
- 6 Benign cysts of the mediastinum are relatively common and include thymic cysts, enterogenous cysts, dermoid cysts, lymphatic malformations (cystic hygromas), and pericardial cysts. Resection is usually recommended because of the possibility of progressive enlargement with compression, hemorrhage, or infection.
- 7 Primary lung tumors in children include bronchial adenoma, rarely bronchogenic carcinoma, pulmonary blastoma, inflammatory pseudotumor (composed of inflammatory cells), and hamartoma. Resection is generally appropriate initial therapy.
- 8 Mediastinal tumors include neurogenic tumors (usually from the sympathetic chain), lymphoma (Hodgkin or non-Hodgkin), teratoma, neurilemmoma, sarcoma, and thymic tumors.
- 9 Tracheoesophageal fistula can occur as esophageal atresia with proximal pouch and distal tracheoesophageal fistula (most common, at 85% to 95%), esophageal atresia without fistula (5% to 7%), tracheoesophageal fistula without esophageal atresia H type (2% to 6%), and rarer forms of this anomaly including esophageal atresia with proximal tracheoesophageal fistula and esophageal atresia with both proximal and distal tracheoesophageal fistula.
- 10 Vascular rings result from faulty embryogenesis of the aortic arch and great vessels resulting in vascular structures and dense connective tissue that surround the esophagus and trachea and can result in symptoms of airway or esophageal obstruction.
- 11 Approximately 200 children die from foreign body aspiration or ingestion each year. Bronchoscopic evaluation and foreign body removal are performed in the operating room under general anesthesia, where the rigid bronchoscope with optical forceps can be used to remove most aspirated foreign bodies safely.
- 12 Left-sided congenital diaphragmatic hernia (CDH) is a 2- to 4-cm posterolateral defect in the diaphragm through which the abdominal viscera have translocated into the ipsilateral thoracic cavity. Through a right-sided defect, the large right lobe of the liver can occupy most of the hemithorax.
- 13 CDH is a physiologic emergency and not a surgical emergency. The newborn with CDH should be stabilized by non-surgical means and delayed, well-planned surgical repair undertaken subsequently.

CHEST WALL DEFORMITIES

Deformities of the chest wall may be obvious at birth but often become more noticeable at the time of preadolescent and adolescent growth. The physical appearance may vary from barely detectable to grotesquely deforming. Although there may be some physiologic benefit from surgical correction of these deformities, restoration of a more normal appearance is equally important in the decision to operate. The impact of these deformities on normal psychosocial development, as well as the less certain evidence of cardiorespiratory impairment, constitutes adequate justification in the affected child.

Embryology, Development, and Etiology of Chest Wall Deformities

In the embryo, the ribs are derived from individual somites as mesoderm differentiates into cartilage and advances ventrally toward the developing sternum. The rib cartilage eventually approaches the sternum. The sternum itself is derived independently from two parallel bands of mesoderm that develop away from the midline. The two sternal bands fuse in a cranial to caudal direction and become progressively chondrified. Transverse divisions of the cartilaginous sternum differentiate into segments opposite each end of the rib pairs. At birth, small

ossification centers are present in the sternum and the ribs have largely ossified. Final ossification is usually complete by mid adolescence. The process is sufficiently predictable that sternal ossification is a reliable method of determining bone age. There is a sharp demarcation in each rib between the ossified portion and the cartilaginous portion, with the latter becoming ossified only much later in life. The etiology of chest wall deformities is poorly understood.¹ Explanations include abnormal intrauterine pressure applied to the chest, abnormalities of diaphragmatic development, connective tissue abnormalities, and genetic predisposition. Abnormal, excessive, or asymmetric growth of the costal cartilages associated with the 3rd to 10th ribs is most implicated. Sternal clefts are understood as a failure of fusion of some portion of the sternal bands.

Pectus Excavatum

1 *Pectus excavatum*, from the Latin phrase “hollowed chest,” is the most common deformity of the anterior chest wall. Pectus excavatum results from abnormal regulation of the growth of the costal cartilages. There is a corresponding posterior curve in the body of the sternum beginning at the manubrium and extending to the xiphoid. The deformity is rarely precisely symmetric, with one side (usually the right) slightly more curved in than the other. Asymmetry may be pronounced with the sternum rotated nearly to the sagittal plane. The deformity may be apparent at birth but may become more apparent during growth and development, particularly during adolescence. Pectus excavatum occurs more frequently in males than females. Another affected relative, most often a father or uncle, is found in one third of cases. Scoliosis is present at increased incidence in this population although rarely requires surgical correction. Patients often have an asthenic build and stoop-shouldered posture. Marfan syndrome predisposes to pectus excavatum. The diagnosis of Marfan syndrome should be considered when patients are referred for evaluation of a chest wall deformity.

At the time of surgical consultation, concerns about the cardiopulmonary implications of the chest wall deformity are often paramount in the mind of the referring physician as well as the family. Many patients will have complaints of chest pain and/or shortness of breath. Most patients are disturbed by the appearance of the deformity, and some may be profoundly

depressed and dysfunctional. The physiologic consequences of the deformity are less certain. Invasive and echocardiographic assessment of cardiovascular performance have demonstrated improvement in cardiac function and resolution of mitral valve prolapse in some patients following surgical correction of pectus excavatum.²⁻⁶ There is no consensus on the exact nature of the cardiopulmonary impairment or on the pulmonary benefit of surgical correction. Although more difficult to measure, the psychological benefit of correcting this severe chest wall anatomic defect has demonstrated excellent results and patient satisfaction.

Clinically, pectus excavatum patients typically complain of chest discomfort and shortness of breath. Dynamic testing can be used to further explore a patient's complaints, but this methodology is not always routinely utilized. Clinical assessment of the severity of the deformity has included chest radiographs, computerized tomography (CT), caliper measurements, and contrast volume measurements of the cavity. The “pectus index” is defined as the ratio of the maximum internal transverse diameter of the thorax to the minimum sternovertebral distance.⁷ If cardiac disease is suspected on the basis of the history and physical examination, an echocardiogram may be indicated. Pulmonary function testing is rarely helpful.

Surgical Correction of the Pectus Excavatum. The ossification of key components of the anterior chest wall is not completed until the teenage years. The further understanding of this physiology has led to a more uniform timing of surgical correction for pectus excavatum in the past decade. Infants and young children should not undergo surgical correction because of the risk of acquired thoracic dystrophy.^{8,9} Most pediatric surgeons agree that the optimal timing is in late childhood and adolescence.

Traditional Operations. Traditional surgical correction^{3,10} is performed through a transverse incision centered on the defect in the line of the inframammary crease (Fig. 106.1). The necessary incision is quite small and may be kept well within the nipple lines. An alternative that may be useful, especially in older females, uses a small incision in each inframammary crease. The operation requires exposure of the costal cartilages by incision into or elevation of the pectoral muscles from the chest wall. Subperiochondrial excision is made to the involved costal cartilages. The 3rd through 7th cartilages are excised

FIGURE 106.1. Pectus excavatum. A: Appearance of an adolescent male with a typical depression deformity. Note “stoop-shouldered” posture. B: Postoperative appearance at 6 months. Erect posture and subpectoral incision give a good cosmetic result.

along with portions of the 8th, 9th, or 10th cartilages if there is particularly prominent flaring of the costal margin. The xiphoid is detached from the sternum, and the rectus muscles are detached inferiorly. The undersurface of the sternum is dissected free from the pericardium and pleura. An anterior osteotomy is created in the sternum at the point where the sternum deflects posteriorly and the posterior cortex is fractured. Closure of the osteotomy elevates the lower sternum. Asymmetric deformities may require insinuation of the osteotome into the sternotomy site on the right and left, which allows rotation of the inferior aspect of the sternum. Some degree of overcorrection is usually performed to help maintain the correction over time. A strut is usually placed beneath or through the sternum to maintain the corrected sternal position. The choice of material and configuration for the strut is variable. Struts may be left in permanently but are usually removed after an interval of 2 to 12 months. The pectoral and rectus muscles are reapproximated. Closed suction drains are used to drain the substernal, submuscular, and/or subcutaneous spaces. Patients are discharged when they are able to tolerate a diet and their pain is controlled by oral analgesics. Drains are removed either as an inpatient or an outpatient. In current practice, patients are often discharged on the second postoperative day. Multimodal pain management including regional anesthesia, postoperative epidural analgesia, nonsteroidal anti-inflammatory agents, and narcotics are used. Complications are generally limited to wound infections and pneumothorax that rarely requires tube drainage. Recurrence rates in large series with long-term follow-up range from 5% to 15%.³ The incidence of reactive pectus carinatum after excavatum repair is 1%.¹¹ Migration of implanted struts and bars has caused the most serious problems, including cardiac injury.

The Lorenz Bar/Nuss Procedure. The Lorenz bar/Nuss procedure has gained widespread popularity. A rigid U-shaped bar inserted transversely across the chest pushes the deformity back into place¹² (Fig. 106.2). The procedure is best performed in late childhood and early adolescence, when there is more pliability of the costal cartilages. Long-term follow-up data is encouraging.¹³ Complications have been reported as the procedure has become more widely practiced, including pneumothorax, cardiac injury, bar displacement, chronic pain, pericarditis, and extraosseous bone formation.¹⁴ The bar is left in for up to 3 years during a period of development when most children are active and may engage in contact sports. Activity restrictions that are necessary while the bar is in place are not well defined. This technique is an important addition to the surgical treatment of chest wall deformities. Recent techniques utilizing thorascopic windows have been developed to hopefully reduce more life-threatening complications such as cardiac injury.¹⁵ Other modifications include dual bar placement, bending the bar in a skewed fashion to correct an angled sternum, and bar placement to correct recurrent pectus excavatum development after an open surgical approach.¹⁶

Other Techniques. Implantation of submuscular silastic molds to alter the chest contour may result in a very acceptable appearance.^{17,18} This technique does not address any of the potential physiologic problems associated with pectus excavatum and has not been used widely.

Externally applied suction may also be used to treat depression deformities of the chest wall.¹⁹ Finally, implanted devices that use magnetic forces to pull the sternum forward show promise in correcting the defect in patients with pectus excavatum.²⁰

FIGURE 106.2. Thorascopically assisted Lorenz Bar insertion (Nuss procedure). A: Preoperative appearance with symmetrical depression deformity. B: Lorenz bar. C: Lorenz bar inserted with thorascopic guidance. D: Immediate postoperative appearance. (Digital images provided by William Hardin, M.D., University of Alabama, used with permission.)

Pectus Carinatum

Pectus carinatum, from the Latin phrase for “keel,” is a chest wall defect where there is a protrusion of the sternum and ribs. ³ This type of defect occurs less commonly than pectus excavatum and presents in approximately 1 in 1,000 teenagers. Physiologic impairment is absent; however, the concern for appearance may be even greater than with depression deformities of the chest wall. Protrusion deformities may be very difficult to hide even when fully clothed. Rapid growth of the costal cartilages occurring during puberty makes the deformity more pronounced at that time. The operative correction of a pectus carinatum deformity is similar to that described for pectus excavatum. An osteotomy and sternal fracture are often not required, but when necessary they are performed in such a way as to depress the sternum. A strut is usually not required to maintain sternal position. The postoperative course and results are similar to pectus excavatum. In the immediate postoperative period, cardiac pulsation may be particularly visible; however, with healing this finding disappears. External compression devices have shown some efficacy in larger trials with a minimal complication rate.²¹ Success depends on prolonged application of the compression device. The Nuss bar has also been applied to force the sternum in a corrective posterior direction.²²

Poland Syndrome

Named after the English surgeon Sir Alfred Poland, this rare congenital syndrome occurs in from 1 in 10,000 to 1 in 100,000 births and includes a range of skeletal and muscle defects. These features include absence of the sternal portions of the pectoralis major muscle; absence of the pectoralis minor muscle; absence of portions of the serratus anterior and external oblique muscles; forearm and hand deformities; ipsilateral hypoplasia of the nipple, breast, and chest wall subcutaneous tissues; absence or deformity of the second to fifth costal cartilages; and absence of axillary hair on the affected side. Surgical treatment includes correction of any deformed ribs, formation of the anterior axillary fold using the latissimus dorsi muscle, and creation of the ipsilateral breast in females.²³

Sternal Clefts

Congenital sternal clefts result from failure of midline fusion of the paired sternal bands. The cleft is usually in the superior portion of the sternum and may extend to but not include the xiphoid. The defects are rare and are usually repaired in the neonatal period when the chest is more pliable.²⁴ The purpose of the correction is to protect the underlying mediastinal structures. After subcutaneous and substernal mobilization, the fibrocartilaginous sternal bars are approximated in the midline. Typically, the cleft is incomplete and a V-shaped excision of the sternum at the most inferior aspect of the cleft may be required to avoid buckling of the sternum in that region.²⁴ Cantrell pentology refers to a distal sternal cleft, omphalocele, diaphragmatic defect, pericardial defect, and intracardiac defect. Thoracic ectopia cordis (exstrophy of the heart) may occur as a part of this abnormality and until recently has been uniformly fatal.

Jeune Asphyxiating Thoracic Dystrophy

Jeune asphyxiating thoracic dystrophy is a rare developmental abnormality that results in the failure of chest wall growth. Surgical correction involves the expansion of the thoracic cavity by rib resection and frame shifting of the ribs. Most recently, the use of a vertical expandable prosthetic titanium rib (VEPTR) device allows division of the most posterior aspect of approximately the third to ninth ribs and division at the costochondral junction of the same ribs. The rib plate is then ele-

vated to the curved VEPTR strut by wires, thus expanding the chest. This is done for both chests, and the device is serially expanded every 4 to 6 months to promote chest enlargement.²⁵

The “Slipping Rib” Syndrome

The slipping rib syndrome is an unusual abnormality that has been ascribed to abnormal development of the costal cartilages along the costal margin such that the 9th or 10th rib is free floating. Positive findings on examination include a click with anterior displacement of the rib by either gently pulling on the inferior costal margin or by pushing on the suspected rib in a lateral direction at the midaxillary line. Patients typically complain of either sharp thoracic or abdominal pain and typically have had a thorough imaging workup that is nonrevealing. Surgical therapy involves excising the involved rib and cartilage, thereby relieving pressure on the involved intercostal nerve.

“Flaring” of the Costal Margin

Patients are sometimes referred for surgical opinions regarding unusual prominence of the costal margin. The “flaring” is most pronounced when the patient is supine. This finding represents a variation of the normal development of the chest wall. Surgical correction should be avoided.

Costochondral “Tumor”

Prominence of a single costal cartilage may present as a concern of a tumor of cartilage or bone. This abnormality is usually found in preadolescents and adolescents. Patients may have undergone a diagnostic workup that includes chest radiographs, ultrasound, CT, or magnetic resonance imaging (MRI) prior to surgical consultation. This abnormality most likely represents a minor variation of a chest wall deformity, such as a pectus carinatum. The area of enlargement is rarely tender so that costochondritis is an unlikely explanation. Excision of the involved cartilage is rarely helpful. Plain radiographs or thoracic imaging are usually sufficient to exclude a tumor.

CONGENITAL CYSTIC DISEASE OF THE LUNG

The most common congenital cystic lesions of the lung result from abnormalities of lung embryogenesis.^{26,27} These lesions include pulmonary sequestration (PS); CCAM, currently known as congenital pulmonary airway malformation (CPAM); bronchogenic cyst (BC); and congenital lobar overinflation (CLO). The first three (PS, CPAM, and BC) are part of the spectrum of bronchopulmonary foregut malformations. The abnormality may be primarily characterized by aberrant blood supply (PS), hamartomatous lung parenchyma (CPAM), or an isolated epithelial cyst (BC). Mixed or intermediate forms that contain elements of more than one abnormality are common.²⁸ The coexistence of these malformations with CDH and congenital heart defects emphasizes that they may be part of a generalized problem with organogenesis. CLO is more likely a secondary response of the developing lung to abnormal compression or obstruction of a bronchus. The retention of fetal lung fluid during critical phases of lung development adversely affects the development of the lung.

Pulmonary Sequestration

⁴ PS are divided into intralobar or extralobar lesions based on their relationship with the investing visceral pleura and adjacent normal lung tissue. Structurally, sequestrations represent

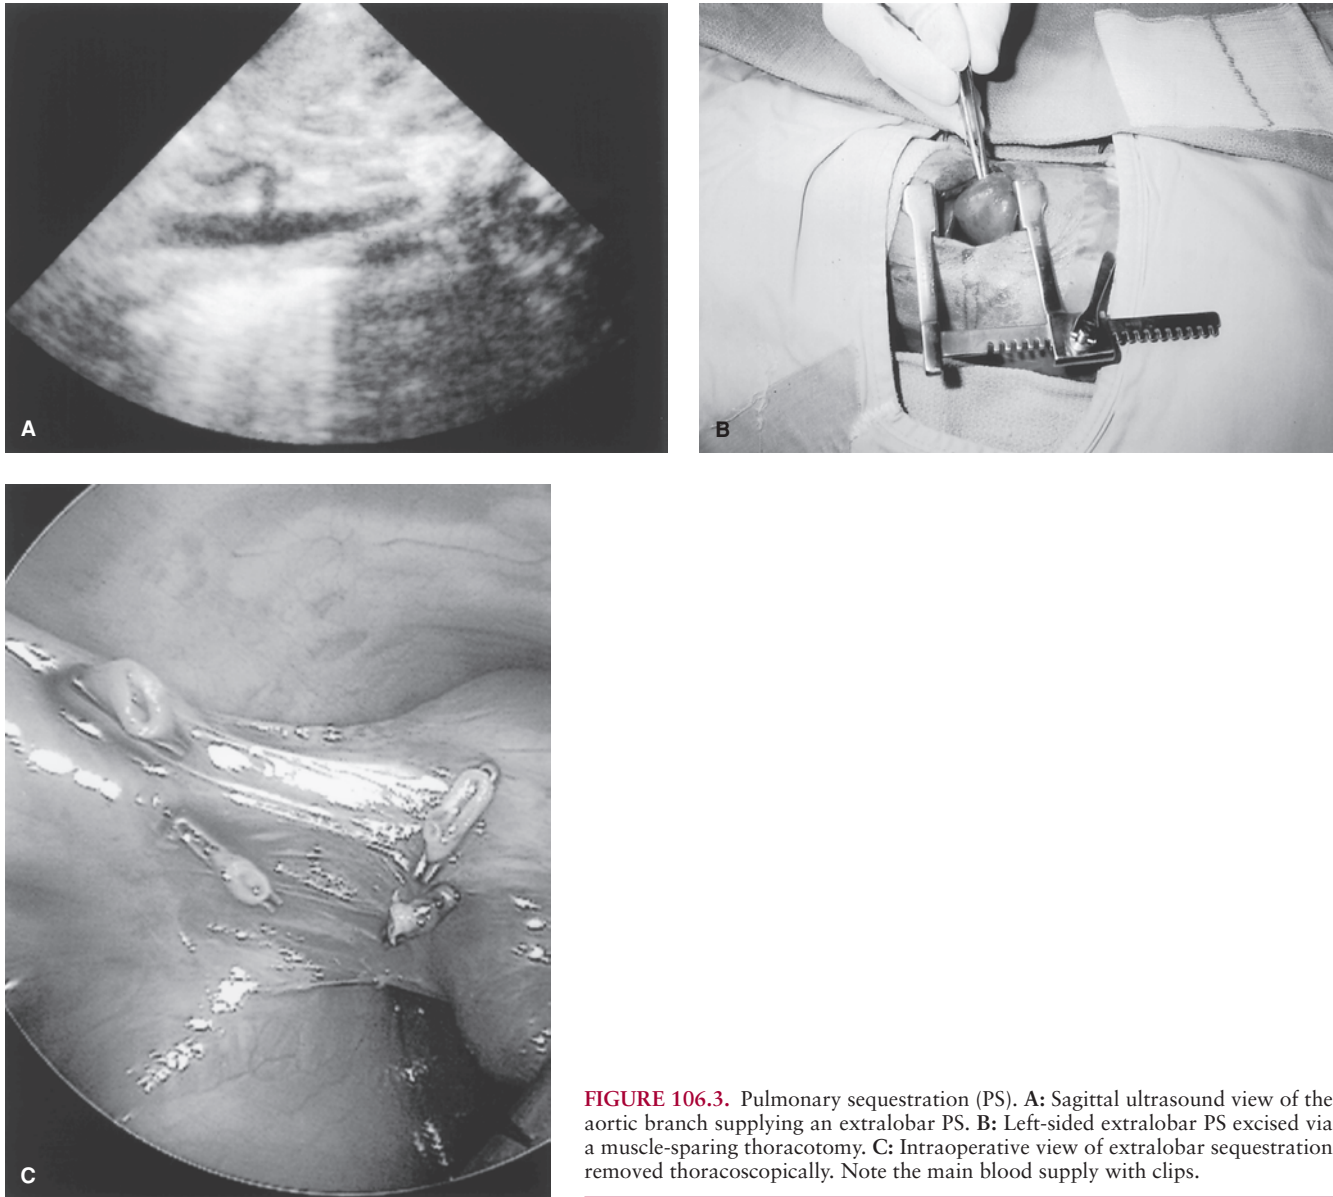

FIGURE 106.3. Pulmonary sequestration (PS). **A:** Sagittal ultrasound view of the aortic branch supplying an extralobar PS. **B:** Left-sided extralobar PS excised via a muscle-sparing thoracotomy. **C:** Intraoperative view of extralobar sequestration removed thoracoscopically. Note the main blood supply with clips.

abnormal lung tissue with anomalous systemic blood supply. They do not communicate normally with the trachea or a bronchus. They are found most commonly in the lower lobes, predominantly on the left.

Intralobar sequestrations lie within a lobe of the lung and are invested by its visceral pleura. They are most common in the posterior segment of the left lower lobe but can occur elsewhere. The anomalous arterial blood supply comes from either the thoracic or abdominal aorta and may traverse the diaphragm to supply the sequestration. Venous drainage from this aberrant tissue may be either pulmonary or systemic but is usually into the pulmonary vein. Aberrant air space connections with adjacent normal lung tissue may permit air trapping within the sequestration, causing it to be aerated on radiographs. Although most often asymptomatic at birth, intralobar PS may present during childhood as recurrent localized pneumonia due to these aberrant air space connections.

Extralobar sequestrations occur outside the pleura of the normal lung. They are most common in the lower left side of the chest but have been reported in various locations, including in the retroperitoneum below the diaphragm.²⁹ In this location, they may be difficult to distinguish from an intra-abdominal tumor such as neuroblastoma. Rarely, extralobar sequestration is associated with CDH. In extralobar sequestration, both the

arterial and venous blood supplies are usually systemic, and the arterial blood supply frequently arises from the aorta below the diaphragm. The lesion itself is usually a spongy consolidated mass with no aeration, which can resemble a congenital pulmonary hemangioma.³⁰ Although infection is rarely present, these lesions can be associated with hemorrhage, arteriovenous shunting, or mediastinal compression. Occasionally, the amount of blood shunted through the lesion is sufficient to result in symptomatic congestive heart failure. Pulmonary malignancies have occurred within these lesions. CPAMs may occur in sequestrations; in fact, sequestrations and CPAMs may be mixed.²⁸

Radiographic evaluation of these lesions involves plain films of the chest and CT scans with care taken to identify a systemic arterial blood supply. Intralobar sequestrations are usually treated with thoracotomy and lobectomy (Fig. 106.3A,B). Sequestrations may be removed with minimally invasive surgical techniques³¹ (Fig. 106.3C). In dealing with both lesions, particular attention must be paid to safe ligation of the vascular supply.

Congenital Pulmonary Airway Malformations

- 5** CCAMs or CPAMs result from excessive proliferation of bronchial structures without the development of the

corresponding alveoli. These malformations have a normal vascular supply and communicate with the normal tracheobronchial tree. On gross appearance, they can be solid, cystic, or both. CPAMs have been classified into three types based on size, shape, spacing of the cysts, and histologic appearance.³² Type I CPAMs are composed of cysts with large irregular and widely dispersed spaces larger than 2 cm in diameter or a single large cyst with small cysts surrounding it. Type II CPAMs consist of multiple cysts less than 1 cm in diameter that are closely packed together and resemble dilated bronchioles. Type III CPAMs are made up of small cysts less than 0.5 cm in diameter, and the parenchymal tissue represents late gestational age fetal lung. Cartilage is usually lacking in all three types of CPAMs. Type I cysts account for almost 50% of cases, while type II cysts make up an additional 40%. CPAMs usually affect only one lobe, but multilobar and bilateral involvement also occurs. The most common lobes affected are the left-sided and lower lobes, although any lobe may be involved. On a molecular level, there have been evidence of at least three genes involved in the development of CCAMs: *HOXB5*, *Fgf7*, and platelet-derived growth factor-B (*PDGF-B*).³³

Prenatal diagnosis is common. In fact, with the advent of prenatal diagnosis, the number of CPAM resections has tripled and the number of asymptomatic CPAMs increased 20% based on the National Inpatient Sample Database (O. S. Soldes, pers. comm.). If the CPAM has sufficient pathophysiologic effects, the fetus may develop life-threatening hydrops. Open fetal surgical resection and thoracoamniotic shunting has resulted in survival of some of these severely affected fetuses.³⁴ As a result of serial prenatal ultrasounds, spontaneous in utero resolution has been observed to occur in as many as one third of these infants.³⁵ Even cystic lesions that are large enough to cause

mass effect on nearby structures may spontaneously regress and not require fetal lobectomy or thoracoamniotic shunting.³⁶

The incidence of CPAM is thought to occur in 1 in 25,000 to 1 in 35,000 live births, and approximately 14% of all CPAM patients are stillborn. Although newborns with CPAM can be asymptomatic at birth, nearly 80% of CPAM patients present with some type of respiratory distress in the neonatal period.³³ The usual radiologic appearance after birth is that of a solid mass because of retained fetal lung fluid (Fig. 106.4A). As ventilation occurs and fluid is reabsorbed, the mass appears larger and cystic and may begin to impinge on surrounding structures (Fig. 106.4B). A less common presentation is the appearance of recurrent pneumonia later in life.

Infants with symptomatic lesions after birth require resection of the involved lobe. Those with severe physiologic affects may require extracorporeal support with resection of the involved lung on extracorporeal membrane oxygenation (ECMO) with excellent expected results. Alternatively, an ex utero intrapartum treatment (EXIT)-to-ECMO approach may be used when gas exchange is predicted to be compromised.³⁷ Asymptomatic lesions can be followed closely to allow for growth and development. In cases where there is no CPAM evident on plain radiograph, a CT scan of the chest should be obtained after birth to document residual parenchymal abnormalities and to look for systemic arterial blood supply.

Operation is clearly recommended if symptoms occur. Although recommendations among pediatric surgeons differ, most recommend elective resection in the setting of asymptomatic CPAM because of the concern for future infection and the possibility of malignancy^{38,39} (see below). Studies have demonstrated that CPAMs evident in the postnatal period rarely spontaneously resolve.⁴⁰ A CT scan prior to operation

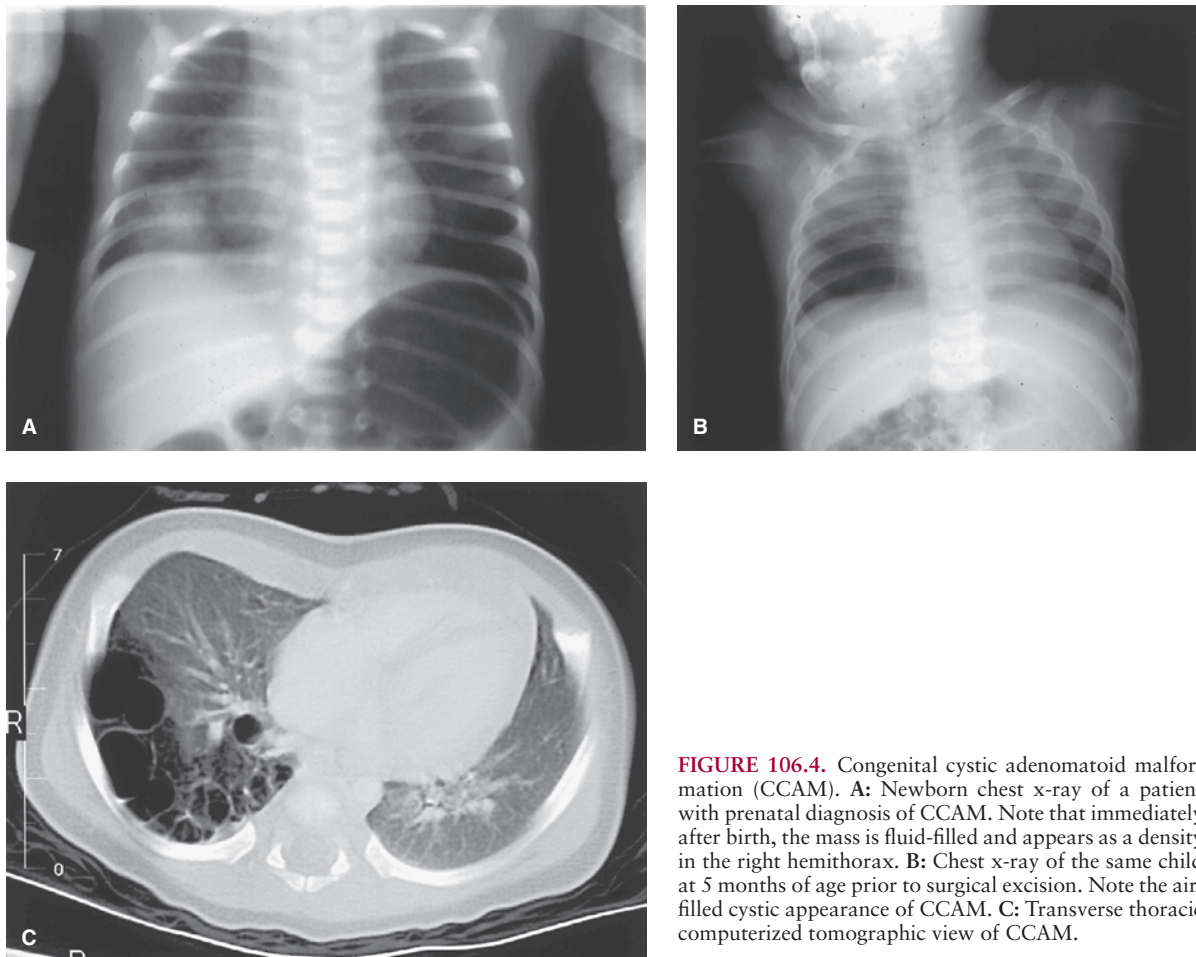

FIGURE 106.4. Congenital cystic adenomatoid malformation (CCAM). **A:** Newborn chest x-ray of a patient with prenatal diagnosis of CCAM. Note that immediately after birth, the mass is fluid-filled and appears as a density in the right hemithorax. **B:** Chest x-ray of the same child at 5 months of age prior to surgical excision. Note the air-filled cystic appearance of CCAM. **C:** Transverse thoracic computerized tomographic view of CCAM.

confirms the diagnosis and assists in surgical planning in infants with asymptomatic lesions (Fig. 106.4C). Elective resection is then performed at 2 to 12 months of age and can usually be accomplished by a minimally invasive approach. Proponents of early intervention point to data demonstrating inflammation in most CPAM specimens, which makes resection more difficult.⁴¹ When bilateral and/or multilobar involvement is found, CT scans may assist in planning lung-conserving resections and in follow-up of residual disease. Lung-preserving resections should be used for CPAMs that involve multiple lung lobes.⁴²

Bronchogenic Cysts

BCs represent groups of epithelial cells from the developing trachea and lung that have become separated from the tracheobronchial tree. These cysts exist as discrete masses, usually in the paratracheal region, and do not incorporate pulmonary mesenchyme on which further lung development is dependent. If cells separate from the bronchopulmonary foregut structures

early in development, these cysts tend to originate from the esophageal portion of the foregut. Separation that occurs later in development is from the ventral or tracheal portion of the foregut, resulting in BCs. BCs are usually extrapulmonary masses that do not communicate with the normal tracheobronchial tree. They do not have a unique blood supply. Resection of these lesions with either a thoracotomy or video-assisted thoracoscopy is recommended because of the risk of bleeding, infection, or enlargement with compression of adjacent mediastinal structures^{43,44} (Fig. 106.5).

Congenital Lobar Overinflation

CLO (previously referred to as congenital lobar emphysema) is caused by abnormal development or compression of a lobar bronchus, resulting in retention of fluid during fetal lung development and subsequent air trapping and overinflation after birth. The lung tissue is intrinsically normal but has been secondarily altered due to the trapping of fluid and gas. The

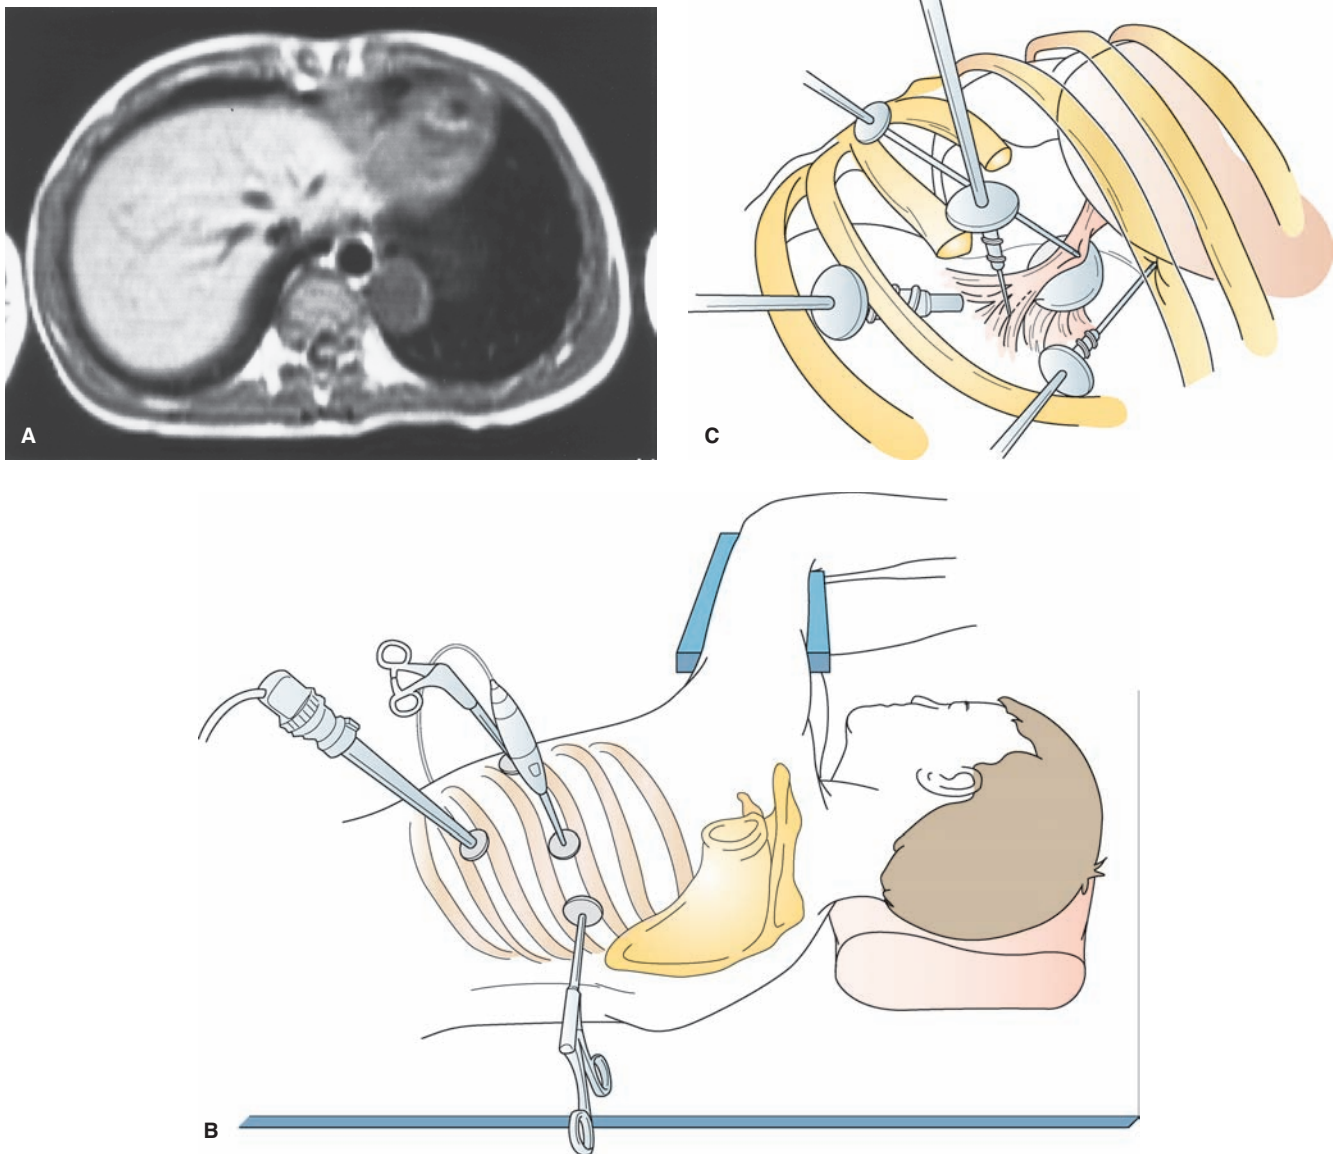

FIGURE 106.5. Bronchogenic cyst (BC). **A:** Transverse thoracic computerized tomographic view of a BC located in the inferior pulmonary ligament. **B:** Illustrative representation of thoracoscopic instrumentation for excision of a BC. **C:** Operative detail. (Adapted from Dillon PW, Cilley RE, Krummel TM. Video-assisted thoracoscopic excision of intrathoracic masses in children: report of two cases. *Surg Laparosc Endosc* 1993;3:433–436.)

FIGURE 106.6. Congenital lobar overinflation. **A:** Chest radiograph demonstrating overinflation of the left upper lobe in an infant. Note the mediastinal shift. **B:** Operative photograph demonstrating an overexpanded left upper lobe decompressing through the incision.

vascular supply is normal. The condition can result from a deficiency of bronchial cartilage that leads to focal airway collapse and bronchial obstruction. CLO can also result from extraluminal bronchial compression due to a BC, an enteric duplication cyst, lymphadenopathy, mediastinal tumor, a vascular abnormality, or congenital heart disease.⁴⁵ In more than half the cases, no obstruction is identified. The upper lobe of either lung field usually is involved, but multilobar involvement has been reported. Lobar overinflation presents as worsening respiratory distress caused by progressive emphysematous enlargement of the involved lobe with compression of normal adjacent tissue and mediastinal shift (Fig. 106.6A). Infants with symptomatic CLO require complete resection of the affected lobe. In selected circumstances, bronchoplasty, bronchial suspension, or relief of an extrinsic bronchial obstruction may be useful. Great care must be taken at the time of anesthetic induction in these infants, as the lobar overinflation may be exacerbated by the institution of positive pressure ventilation. Immediate thoracotomy may be necessary to relieve the compression of the mediastinum and prevent cardiopulmonary collapse (Fig. 106.6B). Up to half of the cases identified will resolve during infancy with observation alone as the lung develops.^{46–48} Surgery is reserved for symptomatic patients.

Diagnosis

With the routine use of prenatal ultrasound, many cystic lesions of the lung are now detected and followed prior to birth.^{35,49} Many of these lesions are completely asymptomatic in the postnatal period. Standard chest radiographs remain the cornerstones of diagnosis and follow-up for these lesions. Rapid thoracic CT scanning provides definitive mapping of these lesions with intravenous contrast. When properly performed, such dynamic images will show the aberrant systemic arterial supply when dealing with a PS. Contrast esophagrams are indicated for children with dysphagia and serve to outline the possibility of an abnormal communication with the gastrointestinal tract. If aberrant vascular supply is suspected but not demonstrated on a CT scan, then MRI angiography of the chest can be obtained.

Treatment

Asymptomatic pulmonary cysts should be removed because of the possibility of infection as well as the rare association of

malignant pulmonary neoplasms in these congenital cysts, including myxosarcoma, embryonal rhabdomyosarcoma, pleuropulmonary blastoma, and bronchoalveolar carcinoma.³³ Any cyst that is enlarging on serial chest radiographs should be resected because of the respiratory compromise that may ensue and the possibility of infection either in the cyst or in the surrounding lung tissue. The only reason for following a lesion in the long term would be if serial CT scans demonstrate progressive resolution, indicating the possibility of an acquired infectious pulmonary cyst, most of which resolve spontaneously.

Cysts of the Mediastinum

- 6 Benign cysts of the mediastinum are relatively common in pediatric patients. Although most of these are completely asymptomatic and discovered incidentally, surgical resection is usually recommended because of the possibility of progressive enlargement with compression, hemorrhage, or infection. When symptoms do develop, they may include chest pain, cough, stridor, hemoptysis, or dysphasia. The common cystic lesions include thymic cysts, enterogenous cysts, dermoid cysts, lymphatic malformations (cystic hygromas), and pericardial cysts.

Thymic Cysts. Thymic cysts are usually asymptomatic and generally have both mediastinal and cervical components located in the superior aspect of the mediastinum. These are benign lesions made up of ciliated epithelium with lymphocytes and cholesterol crystals imbedded in the cyst wall. Clinical problems are usually the result of rapid expansion from either hemorrhage or infection.

Enteric Duplication Cysts/Enterogenous Cysts. Enteric duplication cysts usually occur in the posterior mediastinum and are composed of esophageal or gastric epithelium surrounded by smooth muscle (Fig. 106.7). They are part of the spectrum of bronchopulmonary foregut malformations that include BCs (see above) and esophageal duplications (see below). They may exist completely separate from the structure of origin or may communicate with the gastrointestinal tract above or below the diaphragm. In rare instances, they may attach to or communicate with the spinal canal. A number of large thoracoabdominal enteric cysts have been reported. These cysts may penetrate the diaphragm and end blindly in the peritoneal cavity or communicate with the gastrointestinal tract. If gastric mucosa is present within the cyst, peptic ulceration with erosion and bleeding has

FIGURE 106.7. Enterogenous cyst. This represents another abnormality in the spectrum of bronchopulmonary foregut malformations. **A:** Computerized tomography demonstrating a large mass occupying the right hemithorax. **B:** Surgical specimen.

been reported. Therefore, removal of these cysts is recommended to avoid these possible complications.

Lymphatic Malformations. Lymphatic malformations in the head, neck, and mediastinal region have been classically referred to as cystic hygromas. They are multilocular, thin-walled cysts derived from primitive, aberrant lymphatic sacs. Their mediastinal involvement can be quite extensive, as they insinuate around the great vessels and nervous structures of the superior mediastinum. As with other cystic structures, these lesions are usually asymptomatic. However, with enlargement (most frequently due to hemorrhage) or infection, symptoms may develop with life-threatening potential. Surgical resection of these lesions is usually recommended without sacrificing important anatomic structures within the mediastinum. Most of the intrathoracic components can be resected via a cervical approach. Recurrence develops in approximately one third of cases. Recently, clinical series of successful sclerotherapy of cystic hygromas with large cysts have been reported and may be an effective approach to such lesions.⁵⁰

Pericardial Cysts. Pericardial cysts are almost always asymptomatic lesions discovered as incidental findings on chest radiographs. They appear in the cardiophrenic sulcus as small discrete masses. They are thin-walled cysts containing clear fluid and lined by mesothelium. Resection can be performed with either an open thoracotomy or video-assisted thoracoscopy.

THORACIC TUMORS IN CHILDREN

Thoracic tumors in children are rare. Neoplasms originate from the chest wall, the mediastinum, and the lung. Lung metastases from extrathoracic cancers are more common than primary neoplasms. Surgical treatment may involve removal of the primary tumor, resection of adjacent structures, chest wall reconstruction, lung resection (including wedge resection, lobectomy, pneumonectomy), and tracheobronchial resection and reconstruction. The role of minimally invasive surgery/thoracoscopic surgery is increasing in both the diagnosis and treatment of thoracic tumors in children.⁵¹

Metastatic Lung Tumors

In order for surgical excision of metastatic lung tumors to be beneficial, the primary tumor must be eradicated and the patient should be free of other metastatic disease. Osteogenic sarcoma, other soft tissue sarcomas, and Wilms tumor are the tumors with lung metastases that are most often considered for surgical treatment.^{52,53}

Osteogenic Sarcoma. Although the reported experience in the treatment of metastatic osteogenic sarcoma to the lung is based on retrospective review, there is good evidence that resection of lung metastases is beneficial. The success of surgical removal of metastatic lung disease depends upon effective chemotherapy to eliminate other micrometastatic disease. The metastases are calcified and palpable, which facilitates their surgical removal. Fewer than four nodules, complete resection of all disease, and lack of penetration through the parietal pleura favor survival. Treatment failures and late recurrence are common, mandating careful follow-up. Available data support aggressive attempts at surgical resection, including the removal of many metastatic nodules and multiple resections. A thoracoscopic approach has been felt to be inappropriate by some because of the inability to palpate small lesions.⁵⁴ Prophylactic exploration of both lungs via thoracotomy has also been suggested in order to eradicate small lesions that may not be appreciated on CT.

Soft Tissue Sarcoma. Chemotherapy and radiation-resistant tumors (liposarcoma, leiomyosarcoma, synovial sarcoma, fibrosarcoma, neurogenic sarcoma, epithelioid sarcoma, alveolar soft parts sarcoma) may benefit from resection when the primary tumor has been controlled.⁵³ Rhabdomyosarcoma and Ewing sarcoma are chemo- and radiation sensitive. Lung excision for metastatic disease is generally not helpful, although chest wall resection for a Ewing sarcoma chest wall primary is critical to disease cure. For sarcomas in general, surgery for lung metastases may aid in diagnosis and may be beneficial in removing a large focus of residual disease.

Wilms Tumor. There is little advantage to excision of lung metastases in Wilms tumor. Chemotherapy is required for treatment, and surgical removal offers no added benefit. The

role of whole lung radiation (previously used for lung metastases) will be evaluated in the next phase of the National Wilms Tumor Study under the auspices of the Children's Oncology Group. There are special cases that may benefit from surgery, including very young patients (in whom radiation therapy causes the most lung injury) with few or solitary lesions. Surgery may also be necessary for diagnostic purposes and to determine the effects of therapy. This tissue histiopathologic diagnosis arguably offers more therapy direction than radiographic evidence of indistinct lesions found on CT scans.⁵⁵

Primary Lung Tumors

Reviews by Hartman and Shochat⁵⁶ in 1983 and Hancock et al.⁵⁷ in 1993 have catalogued fewer than 500 reported primary lung neoplasms in children (Table 106.1). Surgical resection remains the mainstay therapy for these primary lesions, and a consensus is developing that surgery may also play a role in metastatic lesions.⁵⁸

Bronchial “adenomas” are the most common primary lung tumors in children. Despite the name they carry, these tumors represent true malignancies. They are better described as low-grade adenocarcinomas of the lung. The incidence of metastasis is low. Histologically, there are three types: carcinoid (85%), mucoepidermoid (10%), and adenoid cystic carcinoma (5%). Bronchial adenomas most commonly arise in primary and secondary bronchi. Presenting symptoms include cough, hemoptysis, airway obstruction, pneumonia, atelectasis, and reactive airway disease. The chest radiographs may show air trapping or pneumonia and atelectasis. The clinical presentation

may be most suspicious for an airway foreign body. CT may demonstrate the lesion. Bronchoscopy is required for diagnosis. Biopsy must be done with great care and with some peril since life-threatening bleeding may result from biopsy attempts. Surgical resection with clean intraoperative margins is the treatment of choice. Resection may involve lobectomy, bi-lobectomy, pneumonectomy, or sleeve resection as well as regional lymphadenectomy with intraoperative frozen section to assure complete tumor resection while limiting lung resection. Bronchial carcinoids are rarely associated with carcinoid syndrome and are radiosensitive if residual disease remains.

Bronchogenic carcinomas are uncommon in children and highly lethal with a mortality rate of 90%. Unlike adults, squamous cell carcinoma is rare; undifferentiated adenocarcinoma predominates. Disease is usually widespread at the time of diagnosis, compromising survival. Rarely, with early discovery and localized disease, cure is possible. Bronchioalveolar carcinoma is a rare lung tumor in children that carries a good prognosis with surgical resection.⁵⁹ This tumor is particularly observed in CPAM lung lesions.⁶⁰

Pulmonary blastoma is a malignant lung tumor occurring most often in children under 4 years of age. It is composed of cells that histologically resemble fetal lung. This tumor usually is located peripherally in the lung and presents with cough, chest pain, and hemoptysis. Pulmonary blastoma is treated by lobectomy, with half of the patients being long-term survivors.

Other Malignant Tumors

Sarcomas, including fibrosarcoma, rhabdomyosarcoma, and leiomyosarcoma, are the next most common primary malignant lung neoplasms found in children. They arise endobronchially as well as peripherally. It is also of note that 9% of all reported malignant lung neoplasms in children were associated with previously documented cystic lung disease.⁵⁷

Inflammatory pseudotumor is the most common “benign” lung tumor in children. Variable nomenclature relates to the description of the inflammatory cells involved. The terms *plasma cell granuloma*, *histiocytoma*, *xanthofibroma*, *fibroxanthoma*, and *inflammatory myofibroblastic tumor* have been used to describe these tumors. They may present as peripheral lesions or as obstructing endobronchial masses, often following a previous pulmonary infection. Symptoms include cough, chest pain, hemoptysis, fever, and airway obstruction (Fig. 106.8). Although there may be some tendency for spontaneous resolution, aggressive local invasion is often seen. As such, it may be more accurate to describe these lesions as low-grade malignancies.⁶¹ Unresectable tumors may respond to nonsteroidal anti-inflammatory agents.⁶² Complete resection, even if extensive in nature, should be undertaken since no adjuvant therapies have proven effective.

Hamartoma. Hamartomatous lung nodules are usually discovered in adults but may be large enough or calcified to be discovered on chest radiographs in children.⁶³ These tumors may be endobronchial and result in airway obstruction or, more commonly, peripheral and asymptomatic unless very large. Conservative pulmonary resection is the best treatment, but large lesions may require lobectomy or even pneumonectomy.

8 Mediastinal Tumors. Mediastinal tumors in children may be benign or malignant. Certain tumors have a predilection for arising from the anterior, middle, or posterior mediastinum.⁶⁴

Neurogenic tumors are the most common thoracic tumors in the pediatric population (Fig. 106.9). The tumors originate in the posterior mediastinum, often from elements of the sympathetic chain. They may grow very large before detection and may be found incidentally. Symptoms of Horner syndrome or tracheal displacement may be apparent. Occasionally,

intraspinal extension results in symptoms of spinal cord compression. Neurogenic tumors may be malignant (neuroblastoma, ganglioneuroblastoma) or benign (ganglioneuroma). Neuroblastoma originating in the mediastinum has a better prognosis than in other sites. The tumors are lower stage and often have more favorable biologic activity such as low amplification of N-myc; however, stage IV mediastinal tumors still have a poor prognosis.⁶⁵ CT and MRI provide anatomic definition of the mass and assess intraspinal extension. There is often widening of the intercostal spaces and enlargement of the spinal foramina at the level of origin of the tumor. All require removal for diagnosis. All but the largest tumors can be removed using a thoracoscopic approach.⁶⁶

Neurofibromas arise from nerves in the posterior mediastinum, such as the intercostal nerves, the phrenic nerve, the vagus nerve, or the sympathetic chain. They may occur as isolated tumors or in association with neurofibromatosis. Scoliosis is particularly common in patients with thoracic neurofibromas. Isolated tumors are readily removed; however, tumors associated with neurofibromatosis tend to extend along nerve sheaths so as to preclude complete removal. Recurrence is to be expected in neurofibromatosis, and malignant degeneration to neurofibrosarcoma can occur in large tumors, mandating periodic monitoring. Neuroblastoma is also increased in patients with neurofibromatosis.⁶⁷

Hodgkin and non-Hodgkin lymphoma may present as an anterior or middle mediastinal mass. Surgical removal is not required, but the pediatric surgeon often participates in the diagnostic workup.⁶⁸ Tissue sampling from cervical lymph nodes, thoracoscopy, or open biopsy may be needed for diagnosis. Special anesthetic risks, including difficulty with ventilation and compromise of cardiac output, exist in the case of bulky anterior mediastinal tumors that compress the large airways. Specifically, patients with greater than 50% reduction in tracheal cross-sectional area or with dyspnea or orthopnea are at special risk.⁶⁹ Under these circumstances, biopsy of a supraclavicular lymph node under local anesthesia or mass biopsy under general anesthesia without paralyzing agents and with ECMO standby should be considered.⁷⁰

Teratomas arise in the anterior mediastinum and may contain elements of all three embryonic germ layers. The lesions are either solid or cystic well-rounded masses that frequently contain calcification on imaging. The most common form of a cystic teratoma consists of mature ectodermal elements known as a dermoid cyst. This lesion is characterized by a thick-walled

fibrous sac with squamous epithelium in which various skin appendages including hair and teeth can be found. Occasionally, they are found within the pericardium. The tumors may be large (Fig. 106.10). Patients typically present with cough, dyspnea, or chest pain, although many will be asymptomatic. Surgical removal of these cysts is indicated because of the risk of infection, erosion into the pleura or pericardium, and local compression. The rare occurrence of malignant components within the tumor mandates assessment of preoperative serum α -fetoprotein and β -HCG and tumor removal.

Other neoplasms of the mediastinum are very rare in children but often require surgical biopsy or extirpation. These include neurolemmoma, pheochromocytoma, primitive neuroectodermal tumors, germ cell tumors, mesenchymal tumors including rhabdomyosarcoma, and thymic tumors.

Chest Wall Tumors. Ewing sarcoma, chondrosarcoma, and liposarcoma are malignant tumors that may originate from the chest wall. Local control of disease may require extensive chest wall excision and prosthetic reconstruction. Primitive neuroectodermal tumors are malignant small-cell tumors that carry a poor prognosis and may involve the chest wall and surrounding tissues. Multimodal therapy with surgery, chemotherapy, and radiation may be of benefit.^{71,72}

Respiratory Papillomatosis. Recurrent respiratory papillomatosis is a viral-induced disorder caused by the same human papilloma viruses that cause genital condylomata.⁷³ It is likely transmitted at birth, and there may be some protective prophylactic benefit from cesarean section in selected high-risk expectant mothers. Airway-obstructing papillomas develop in the first several years of life and are treated with laser ablation. Often, many sessions are required to clear the airways. Children who develop symptoms before age 3 years are more likely to have severe disease.⁷⁴

ESOPHAGEAL ATRESIA/ TRACHEOESOPHAGEAL FISTULA

Esophageal atresia and tracheoesophageal fistula were first described by Thomas Gibson in 1697. A London-based physician, Gibson visited a baby who was unable to swallow without constant regurgitation of food. At autopsy, Gibson discovered two blind ends of esophagus that did not interconnect.

FIGURE 106.10. Medial teratoma. **A:** Transverse thoracic computerized tomography of a large anterior mediastinal teratoma presenting with airway compression symptoms in a 9-month-old female. **B:** Tumor removal via a median sternotomy.

As the subjects of anatomy and physiology exploded with new information, the understanding of esophageal atresia and fistula drastically improved. Initial attempts at both corrective and palliative surgery in the early part of the 20th century were unsuccessful. On March 15, 1941, Dr. Cameron Haight performed the first successful primary repair of esophageal atresia at the University of Michigan.⁷⁵ Refinements in surgical technique and postoperative critical care have resulted in a steady improvement in survival for such patients over the ensuing five decades.⁷⁶ In the modern era, survival is determined almost exclusively by severe prematurity and the presence of associated anomalies, in particular cardiac disease, and not by the esophageal abnormality itself.⁷⁷

Embryology

Development of the human respiratory tract begins as primitive epithelial cells branch off of the ventral foregut of the embryo into the surrounding mesenchyme at the beginning of the fourth week of gestation. There are ongoing processes that involve both elongation and separation of the foregut (esophagus) and the airway (trachea). By the end of the fourth week of gestation, the esophagus and trachea have completely separated to the level of the larynx. This developmental program is under the control of master regulatory genes that are turned on and off in an orderly fashion. Interruption of this developmental process during the fourth week of gestation probably results in the various forms of esophageal atresia with or without tracheoesophageal fistula. By the end of the sixth week of gestation, the circular muscular coat of the esophagus develops, followed by vagal innervation. The segmental blood supply from the aorta appears by the seventh week, and the muscular coat has differentiated into two layers by the ninth week. The malformation can be recapitulated in an animal model by the administration of Adriamycin at specific times and doses to pregnant rats during organogenesis.^{78,79}

Classification

- 9 Descriptive terminology is used to indicate the anatomic configuration of a patient with esophageal atresia (Fig. 106.11). Esophageal atresia with proximal pouch and distal tracheoesophageal fistula is by far the most common type encountered by the pediatric surgeon, accounting for 85% to 95% of all cases.

Esophageal atresia without fistula (pure atresia) occurs in 5% to 7% of patients. Tracheoesophageal fistula without esophageal atresia (so-called “H-type” or “N-type” fistula) occurs in 2% to 6% of patients. The more rare forms of this anomaly include esophageal atresia with proximal tracheoesophageal fistula and esophageal atresia with both proximal and distal tracheoesophageal fistula. The frequency of these rare forms is less than 1% in most reports. Alphabetical and numeric classification schemes, devised by Haight,⁸⁰ Gross,⁸¹ and Kluth⁸² are of historical interest. The most common variety (proximal pouch, distal fistula) is still commonly referred to as “Gross type C.”

Incidence and Epidemiology

The incidence of esophageal atresia varies among populations and races in the range of 1 in 2,500 to 1 in 20,000 births. The overall incidence is about 1 in 5,000. There is a slight male preponderance of 1.26:1. First pregnancy, advanced maternal age, hormonal exposure in pregnancy, and an affected parent and affected siblings are risk factors. Chromosomal abnormalities, twinning, and associated anomalies are more common than expected.

Clinical Findings, Diagnosis, and Pathophysiology

The diagnosis of esophageal atresia may be suspected by the finding of maternal polyhydramnios. Specific ultrasonic identification of the blind-ending upper pouch may be diagnostic. However, many patients go undiagnosed until after birth. Most infants are asymptomatic in the first hours of life. Excessive drooling may be noted. Choking, coughing, and regurgitation may be present and worsened by attempts at feeding. Respiratory distress and cyanosis due to aspiration may occur. Occasionally, in the breast-fed infant, the diagnosis may be unrecognized for more than a day as the volume of feeding associated with colostrum ingestion prior to milk flow may be very low. The inability to pass a nasogastric or orogastric tube is confirmatory of the diagnosis. Radiographs confirm the position of the tube in the proximal blind-ending pouch. Injection of air during the radiograph outlines the pouch. The child with esophageal atresia and a tracheoesophageal fistula will have a full abdomen and gas visible throughout the bowel on the abdominal radiograph. A scaphoid abdomen and gasless

FIGURE 106.11. The anatomy of the variants of esophageal atresia and tracheoesophageal fistula (TEF). **A:** Proximal pouch with distal TEF (most common type occurring in 85% of patients; Gross type "C"). **B:** Esophageal atresia without TEF (5%). **C:** TEF without esophageal atresia (<5%). **D:** Esophageal atresia with proximal and distal TEF (rare). **E:** Proximal TEF and distal pouch (rare). (After Manning PB, Morgan RA, Coran AG, et al. Fifty years' experience with esophageal atresia and tracheoesophageal fistula. *Ann Surg* 1988;204:446.)

radiograph indicate pure esophageal atresia with no fistula. Isolated tracheoesophageal fistula without esophageal atresia does not result in esophageal obstruction and therefore is diagnosed later in infancy or childhood as a result of respiratory symptoms such as aspiration pneumonia, choking with feeds, and gastric distention with crying. Exact delineation of the anatomy may require endoscopic evaluation at the time of surgical correction (Fig. 106.12). If a distal fistula is present, gastroesophageal reflux into the respiratory tract will result in chemical pneumonitis. This may be made worse by air distention of the stomach through the fistula. This is less of a problem if the respiratory tract is mature and the infant can breathe normally. If significant respiratory failure is present, lung compliance is decreased, and positive pressure mechanical ventilation is required, ventilating gases may flow preferentially through the fistula into the gastrointestinal tract. Progressive abdominal distention may preclude adequate ventilation

requiring emergency decompression of the stomach and control of the fistula.

Associated Anomalies

Associated anomalies are present in about half of newborns with esophageal atresia, indicating that other systems are affected by the early organogenic insult that disturbs the development of the trachea and esophagus. The most common associated anomalies are cardiovascular defects. Genitourinary, gastrointestinal, skeletal, neurologic, and craniofacial defects are found with increased frequency in patients with esophageal atresia as well. The particular occurrence of vertebral anomalies, anorectal malformations, and cardiac, tracheoesophageal, renal and (radial) limb defects is known as the VACTERL association. Two or more of these defects need to be

FIGURE 106.12. Bronchoscopic view of the trachea in a patient with common esophageal atresia and tracheoesophageal fistula (TEF). Note that during the inspiratory phase of positive pressure ventilation the fistula opens widely, demonstrating the “face” of TEF (lower left). The more proximal view in the trachea demonstrates tracheomalacia with coaptation of the anterior trachea and posterior membranous trachea (lower right).

present to assign the association to a given patient. Nearly half of tracheoesophageal atresia patients will exhibit one of the VACTERL malformations.⁸³

Preoperative Treatment

Preoperatively, attempts at feeding are stopped and intravenous fluids are started. Further aspiration is minimized by placement of a sump catheter in the upper esophageal pouch. To avoid further lung injury, antacids and antibiotics should be considered. Additionally, standard precautions such as head-up positioning should be universally accepted. Endotracheal intubation is avoided unless necessary since positive pressure ventilation may result in preferential flow of ventilatory gases through the fistula. Ventilation strategies such as high-frequency oscillatory ventilation (HFOV) should be employed if respiratory failure is associated with decreased lung compliance and to potentially avoid filling the stomach with gas. Early use of surfactant to improve lung compliance should be considered in premature infants with respiratory failure. Bedside decompressive gastrostomy may be needed if gastric distention compromises ventilation or a prolonged interval is planned prior to surgery. One of the more difficult issues in pediatric surgery is the decision making around ligating the fistula in a newborn with esophageal atresia and distal tracheoesophageal fistula prior to onset of severe respiratory insufficiency. The

lung retraction required to ligate the fistula is prohibitive once respiratory insufficiency has progressed. Thus, the surgeon must be prepared at the first signs of respiratory compromise to control the fistula by emergency operative ligation. An alternative is to place an occluding distal esophageal balloon via a gastrostomy under fluoroscopic guidance or bronchoscopic guidance if ventilation cannot be maintained.⁸⁴

The goal of modern operative treatment is to correct the anomaly completely with a single operation, avoiding a gastrostomy if possible. Immediate surgery is rarely required, and a day or two may be utilized to complete the assessment of the infant, including the echocardiographic evaluation to determine the position of the aortic arch and the presence of structural heart disease. This time period will also allow a complete transition from fetal circulation. Respiratory hygiene, positioning, and antibiotics may improve the infant's overall condition.

High-risk infants who cannot safely undergo surgical correction of their esophageal abnormality may be treated with delayed repair. A decompressive gastrostomy, proximal pouch suctioning, and parenteral nutrition are used until the infant is ready for operation. Severe respiratory failure (usually from prematurity) and structural heart disease are the most common reasons to delay esophageal surgery. A staged repair that employs gastrostomy, surgical division of the tracheoesophageal fistula, followed by esophageal anastomosis as a second thoracic operation is rarely used except as a lifesaving approach.

FIGURE 106.13. Patient with pure esophageal atresia treated initially with feeding gastrostomy, and proximal pouch stretching. This “gapogram” demonstrates close approximation of a dilator in the proximal pouch and a probe placed in the distal esophagus via the gastrostomy. The child subsequently underwent primary repair of the esophagus.

In the case of pure esophageal atresia without fistula, a prolonged period of delay prior to repair may be used to improve the likelihood of completing a primary repair of the esophagus. A feeding gastrostomy is performed initially. This may be technically challenging since microgastria is present with pure atresia. Intra-gastric feeding and somatic growth result in shortening of the interval between the upper pouch and lower esophageal segment over the course of several weeks. The upper pouch may be stretched by daily or twice-daily passage of a blunt flexible bougie. Radiographic determination of the distance between the two esophageal ends guides the timing of operation (Fig. 106.13).

The Waterston classification stratified infants into good, moderate, and high-risk groups based on birth weight, pneumonia, and associated anomalies.⁸⁵ The risk group was used to help determine the timing and staging of surgical correction and to compare the results at different centers. Low birth weight/prematurity has less of an impact on survival than in the past. Currently, the presence of major cardiac disease and chromosomal abnormalities are the most important predictors of survival.^{86–89}

Surgical Technique

In most patients, it is not necessary to perform a gastrostomy at the time of repair. With typical anatomy (left aortic arch), the repair is performed via a right thoracotomy (Fig. 106.14). Although the approach may be either transplurular or extrapleural, the extrapleural approach is preferred by most pediatric surgeons. A standard posterolateral right thoracotomy may be employed. There is no need to divide the latissimus or serratus muscles, and a muscle-sparing approach may have long-term benefits.⁹⁰ A more posterior approach through the auscultatory triangle affords excellent exposure with a very

small skin incision. The extrapleural plane is established at the fourth intercostal space and developed sufficiently to allow control of the fistula and adequate mobilization of the proximal pouch. The distal tracheoesophageal fistula is divided and closed. The proximal pouch is identified and mobilized to whatever extent is needed to bring the ends together for anastomosis. If a proximal fistula is present, it is closed.

Various lengthening techniques may be used when the gap is long between the esophageal ends. These techniques include circular myotomies, spiral myotomies, flap tubularization of the proximal pouch, and extensive mobilization of the proximal pouch through a supplementary cervical incision. Contrary to earlier teaching, the distal esophagus may be mobilized as well when there is a long distance between the upper pouch and lower esophagus, or in the case of pure esophageal atresia. Distal mobilization may extend to the stomach. An anastomosis may heal, even under tension. One-layer, two-layer, and end-to-side repairs have been used. Most surgeons use a single layer end-to-end anastomosis.

A staged repair has been described that has been successfully employed in pure and long gap esophageal atresia. Traction sutures are initially placed in the upper pouch and lower segment. Daily tensioning results in lengthening of the esophagus that allows anastomosis within a few weeks⁹¹ (Fig. 106.15).

In the worst cases of long gap atresia, pure atresia, or failed initial operative repairs, esophageal replacement may be performed at a later date using stomach, gastric tube, or colon.^{92–94} Such conditions may be temporized with a cervical esophagostomy (“spit fistula”) and gastrostomy with initiation of sham feeds.

Tracheoesophageal fistula without esophageal atresia is referred to as H-type atresia. The orientation of the fistula is such that the opening into the trachea is always proximal to the esophageal entry site. Repair is performed through a cervical approach after bronchoscopically stenting the fistula with a small catheter. The catheter aids in the precise identification of the fistula during dissection in the neck. Care must be taken to stay in the plane of the esophagus to avoid injury to the recurrent laryngeal nerves.

Minimally invasive techniques using modifications of thoracoscopy may be used to treat esophageal atresia.^{95,96} In fact, the thoracoscopic approach is now used by many surgeons with equivalent outcomes except, perhaps, an increased rate of stricture formation.⁹⁷

Results, Complications, and Outcomes. Technical mishaps during the procedure occur when the anatomy is misidentified or dissection is carried out improperly. Unplanned injury to the vagus nerves, recurrent laryngeal nerves, posterior trachea, and adjacent vessels must be avoided.

Anastomotic leak is said to occur in 10% to 20% of patients. The vast majority of such leaks will heal spontaneously. The presence of a leak prolongs hospitalization and increases the likelihood of stricture formation at the anastomotic site. When a leak is detected, the retropleural chest tube is left in place, the infant is not fed by mouth, and antibiotics may be administered. Repeat contrast documents healing prior to the initiation of feeds.

Esophageal stricture at the site of the repair is found in as many as 40% of patients after repair. Many strictures will respond to a few sessions of dilation. Dilations are performed in the operating room with endoscopic and fluoroscopic assistance, as necessary, to assure the safe traverse of the narrowing by guide wires and dilators. More recalcitrant strictures may require many dilation sessions, steroid injection, and medical or surgical control of gastroesophageal reflux for resolution. Occasionally reoperation, with resection of the stricture and reanastomosis of the esophagus, may be required.

Recurrent tracheoesophageal fistula is reported to occur in up to 10% of patients. Recurrent fistulas may respond to endoscopic ablation, a combined Tisseel/Gelfoam construct

FIGURE 106.14. **A:** Schematic illustration of esophageal atresia with distal tracheoesophageal fistula. **B:** The initial management of this anomaly includes upright or prone posture, sump suction of the blind esophageal pouch. **C:** The right extrapleural operative approach. After division and closure of the fistula, primary esophagoesophagostomy is performed. (After Coran AG. Congenital abnormalities of the esophagus. In: Zuidema GD, Orringer MD, eds. *Shackelford's Surgery of the Alimentary Tract*. 2nd ed. Philadelphia, PA: WB Saunders; 1990.)

placed into the fistula, or require operative division with interposition of pleura, muscle, or pericardium.

Gastroesophageal reflux is present in nearly all infants with esophageal atresia. It is symptomatic in many and may contribute to respiratory symptoms and stricture formation.

FIGURE 106.15. In patients with ultra-long-gap esophageal atresia, traction sutures are placed on the upper pouch and lower segment. Tension is increased daily until the segments lengthen, allowing primary repair. (Adapted from Foker JE, Kendall TC, Catton K, et al. A flexible approach to achieve a true primary repair for all infants with esophageal atresia. *Semin Pediatr Surg* 2005;14:8–15.)

Medical treatment consists of thickened feedings, upright positioning after feeds, frequent burping, small frequent feeds, acid reduction, and prokinetic agents. In many infants, medical treatments will be inadequate to control symptoms and surgical control of reflux will be required.

Esophageal dysmotility is present to some degree in all patients with esophageal atresia. Dysmotility contributes to gastroesophageal reflux and may be responsible for dysphagia and recurrent respiratory problems.

Tracheomalacia may result in symptoms after the correction of esophageal atresia. Bronchoscopically, the trachea appears oval in shape rather than round. The anterior and posterior walls coapt during the respiratory cycle (Fig. 106.12). Fluoroscopic examination of the trachea demonstrates narrowing or “fish-mouthing” in the anteroposterior dimensions during spontaneous expiration. Tracheomalacia “fits” occur as the infant becomes agitated and develops worsening chest retractions with inspiration. The condition may deteriorate to complete inspiratory block and unconsciousness. When spontaneous respiration resumes in a quiet fashion, the “spell” is over. Intubation and resuscitation may be required. The symptoms are completely relieved by endotracheal intubation. Infants with less severe symptoms may improve over time as the trachea grows. Severe symptoms require either tracheostomy or tracheal suspension with an aortopexy under bronchoscopic guidance to ensure effectiveness of the aortopexy. There can be difficulty in determining whether cyanotic spells or an acute life-threatening event are due to tracheomalacia or gastroesophageal reflux. Data from bronchoscopy to evaluate the

degree of tracheomalacia and upper gastrointestinal radiography and pH probe to assess for reflux can be combined with symptoms noted prior to the event to help lead the surgeon toward an operation to resolve the most likely of the two problems.⁹⁸

Long-term results have improved in patients with esophageal atresia. Most children can look forward to survival with a normal existence.^{99–103} Overall survival rates are reported in the 85% to 95% range. However, there are subsets of infants who do not fare as well. The mortality rate is high for infants with severe congenital heart defects and chromosomal abnormalities. Late deaths related to respiratory disease (tracheomalacia, reactive airway disease, gastroesophageal reflux, aspiration) can occur.⁸⁸ The very long term outcomes for children with repaired esophageal atresia are not known. Disordered peristalsis and chronic esophagitis may have long-term implications such that periodic endoscopic surveillance of the esophagus should be performed in select patients.¹⁰⁴

OTHER CONGENITAL ABNORMALITIES OF THE TRACHEA AND ESOPHAGUS

Laryngotracheoesophageal Cleft

Laryngotracheoesophageal cleft (LTEC) abnormalities represent the most severe anomalies of development of the trachea and esophagus. Type I abnormalities communicate at the level of the larynx and cricoid. Type II abnormalities extend beyond the cricoid into the cervical trachea. Type III LTEC involves the entire trachea from the larynx to the carina. The embryogenesis of LTEC is poorly understood but likely represents a disruption similar to but more severe than the more common esophageal atresia/TEF abnormality. Associated abnormalities of the cardiovascular system and genitourinary and gastrointestinal tracts are common. In patients with type I and II defects, esophageal atresia and a distal tracheoesophageal fistula is present about a third of the time.

Type I clefts may be repaired via an endoscopic or transalaryngeal approach. Type II clefts require cervical exposure, either laterally or by dividing the larynx and trachea in the midline. This anterior midline approach provides excellent exposure and avoids injury to the recurrent laryngeal nerves. Type III clefts extending to the carina, or beyond, require direct exposure through a right extrapleural thoracotomy as well as cervical exposure. The trachea and esophagus are separated longitudinally in such a way as to leave a remnant of the esophagus with the trachea to be used in reconstructing the posterior membranous portion of the trachea. The esophagus is then tubularized. A multilayered repair of the larynx is completed through the cervical exposure. Breakdown of the repair and prolonged need for tracheostomy are common. Oromotor dysfunction and chronic aspiration are long-term problems. Most children will require a gastrostomy for feedings. Gastroesophageal reflux is common and may require surgical control.

Congenital Esophageal Stenosis

Acquired peptic strictures of the esophagus are relatively common and may occur early in life. True congenital stenosis is very uncommon. The stenotic areas may be (a) a membranous, web-like diaphragm; (b) fibromuscular thickening characterized by submucosal proliferation of smooth muscle cells and connective tissue; or (c) due to sequestration of respiratory tract remnants in the form of respiratory epithelium and cartilage. The cartilage remnants may form a complete nondistensible ring in the esophagus. Dysphagia may be present from infancy or become apparent when solid foods are introduced. The diagnosis is confirmed by esophagoscopy. Stenoses are initially treated with

FIGURE 106.16. Thoracoscopic excision of an esophageal duplication cyst in a patient presenting with dysphagia. Video endoscopic view of the left superior hemithorax. (+) indicates site of original esophageal duplication cyst. Light from the intraesophageal endoscope can be seen. Arrows demonstrate the subclavian artery. The mass (*) is nearly excised.

dilations. Stenosis due to respiratory tract remnants is more likely to require segmental resection of the involved area.

Esophageal Duplication

Esophageal duplications are found in the posterior mediastinum and are covered by a muscular wall that is in continuity with the muscular wall of the esophagus. The epithelial lining is usually intestinal, often gastric, mucosa and does not usually communicate with the esophagus. These cysts may also have a respiratory epithelium lining underscoring the relatedness of the various bronchopulmonary foregut malformations. Neurenteric cysts will communicate with the spinal canal. Masses are discovered incidentally or as a result of compression on adjacent organs. Acid-peptic ulceration from gastric mucosa within the cyst may result in symptoms such as pain, bleeding, or erosion into adjacent structures (lung parenchyma, bronchus, esophagus). Excision is recommended. Thoracoscopic techniques allow excision with minimal morbidity (Fig. 106.16).

Vascular Rings

10 Vascular rings result from faulty embryogenesis of the aortic arch and great vessels. In these abnormalities, the esophagus and trachea are surrounded by vascular structures and dense connective tissue that results in symptoms of airway or esophageal obstruction. Symptoms include wheezing, noisy breathing, coughing, stridor, pneumonia, and dysphagia (often when solid foods are started). A barium swallow may be suggestive or diagnostic. CT and MRI are used to define the anatomic abnormality. Echocardiography is used to rule out structural heart disease.

The most common abnormality encountered is a double aortic arch, resulting from the persistence of both the left and the right embryologic aortic arches. The ascending aorta bifurcates, surrounding the trachea and esophagus, then rejoins as the descending aorta. Other developmental abnormalities may result in complete or incomplete rings that compress the trachea and/or the esophagus. When the vascular ring is

symptomatic, the patient should be treated surgically by appropriate division of the ring and the lysis of the fibrous bands that surround the trachea and esophagus.

Congenital Tracheal Stenosis

Failure of tracheal growth and development results in a wide variety of abnormalities. Short segments of the trachea may be narrowed, or the entire trachea may be hypoplastic. Often, complete tracheal cartilaginous rings are present. Short stenotic areas may occasionally respond to balloon dilation, which splits the complete tracheal rings. Segmental stenoses may be amenable to resection and anastomosis. Longer stenoses may be corrected with placement of a graft to widen the lumen of the trachea. Most recently, the slide tracheoplasty technique has been used to reconstruct narrowed regions of the trachea.^{105,106}

FOREIGN BODIES OF THE TRACHEOBRONCHIAL TREE

11 Foreign body ingestion and aspiration occur commonly in the pediatric population. Endoscopic removal of foreign bodies that lodge in the esophagus is covered in Chapter 45. Any foreign body that could obstruct the airway represents a potentially life-threatening problem. The National Safety Council estimates that 200 deaths (most in children under 5 years of age) occur each year in persons under the age of 15 years as a result of suffocation by an ingested object.¹⁰⁷ The Hopkins rod lens optical system with fiberoptic illumination, developed in the 1970s, combined with rigid pediatric bronchoscopes and specialized grasping devices has resulted in a safe and reliable method for airway foreign body extraction.

Pathophysiology

Complete obstruction of the airway and asphyxiation can occur at the level of the laryngeal inlet, the subglottis, or the trachea. Back blows (recommended in infants), abdominal thrust, or the Heimlich maneuver may dislodge the obstruction and save a

life. An inhaled foreign body that lodges at the bronchial level can create a ball-valve phenomenon in the affected bronchus, allowing bi-directional but unequal flow of air. Air trapping and hyperinflation in the affected lobe or lung leads to mediastinal shift to the opposite side. Complete blockage of the bronchus by the foreign body results in loss of volume in the affected lobe or lung. In this case, the resulting volume loss from atelectasis will shift the mediastinum to the ipsilateral side.

Clinical Presentation

Most affected children are under 4 years of age, with a peak incidence between 1 and 2 years. Twenty percent of foreign body aspirations occur after the age of 4 years. Foreign bodies are more likely to lodge in the right side of the tracheobronchial tree. Most will be found in the main stem bronchus.¹⁰⁸ Peanuts are commonly aspirated and particularly troublesome. They become soft, fracture readily, and may require piecemeal removal. Other types of food, such as carrots and popcorn, or inorganic material, such as pins, wood, paper, and metallic and plastic parts, may be aspirated.

The aspiration event may have been witnessed or suggested by a history of a coughing or choking spell. The most common symptoms include cough, wheezing, dyspnea, and fever, while the most common signs are unilateral decreased breath sounds, unilateral wheezing, and rhonchi. Inspiratory and expiratory chest radiographs (or bilateral decubitus views in the case of children too young to cooperate) may demonstrate hyperinflation on the affected side due to air trapping. Although physical signs, symptoms, and radiographic findings are often present, a suggestive history alone is an adequate indication to proceed with bronchoscopy.¹⁰⁹

Management

Bronchoscopic evaluation and foreign body removal is performed in the operating room under general anesthesia (Fig. 106.17). The rigid bronchoscope with optical forceps can be used to remove most aspirated foreign bodies safely. The flexible grasper, Fogarty balloon catheters, and baskets can be useful, especially when the foreign body has migrated distally or has

FIGURE 106.17. Schematic illustration of a peanut foreign body being extracted from the right main stem bronchus under direct vision.

FIGURE 106.18. Four-panel operative photograph of the removal of a pin from lung periphery. The tip of the pin is seen on the lung surface. Thoracoscopic instrumentation. Grasping pin. Pin removed.

a smooth or round surface. Fluoroscopic assistance has been used for radiopaque objects that have migrated into the peripheral airways.

Over time, pneumonia or atelectasis may develop in the lobe or lung associated with a foreign body. Occasionally, foreign body aspiration that presents as a chronic lung infection will require surgical resection of the associated portion of the lung. Figure 106.18 shows the fluoroscopically assisted thoracoscopic removal of an aspirated pin that migrated to the peripheral lung surface.

CONGENITAL ABNORMALITIES OF THE DIAPHRAGM

Developmental defects of the diaphragm are of great interest to pediatric surgeons. Advances in the treatment of newborn respiratory failure, fetal surgery, and lung developmental biology have grown directly out of the clinical and laboratory investigation of CDH (Bochdalek hernia). Occurring in approximately 1 in 3,000 newborns, this relatively rare congenital disease represents a significant area of research within the clinical and basic science research community.

McCauley¹¹⁰ described the clinical course and post-mortem anatomy of an infant with CDH in 1754. Although

Bochdalek's¹¹¹ understanding of the embryology was incorrect, this congenital defect continues to carry his name. Successful repair of CDH remained rare prior to 1940.¹¹² In 1946, Gross¹¹³ reported the first infant less than 24 hours old surviving operative repair of the defect. The standard of care remained immediate neonatal surgery until the 1980s. CDH was considered to be an anatomic derangement that was treated by an anatomic correction (i.e., the surgical solution was to "get the bowel out of the chest" and "prevent further lung compression from the intestines").

During the last 25 years, greater emphasis has been placed on the physiologic behavior of the lungs in CDH. Lung function, as determined by the degree of pulmonary hypoplasia and pulmonary hypertension, is the most important determinant of survival in CDH. With endotracheal intubation, gastric decompression, and positive pressure ventilation at low ventilator pressures, there is very little consequence to the presence of the abdominal viscera in the chest. Surgery may be delayed almost indefinitely, if necessary.¹¹⁴ Pulmonary hypertension is aggressively treated by whatever means necessary, and surgical repair is performed when labile pulmonary hypertension has resolved. Improved survival of infants with CDH has resulted from a better understanding of the physiology of postnatal pulmonary hypertension and changes in the timing of surgery. Better treatments for pulmonary hypertension and

therapies aimed at augmenting the development of hypoplastic lungs will no doubt result in further improvements in the survival and long-term morbidity of CDH infants.¹¹⁵

Embryology of the Lung and Diaphragm

Mammalian lung development occurs *in vivo* as a coordinated developmental process that includes (a) airway and acinar development, (b) cellular differentiation, (c) biochemical maturation, (d) interstitial development including vasculature and extracellular matrix, and (e) physical growth or enlargement. These parallel developmental processes occur in such a fashion that at any one time during development, there are characteristic relationships among each component that define the so-called stages of lung development.^{116–118} Pulmonary development is marked by a series of programmed events regulated by master genes such as the homeobox genes, nuclear transcription factors, hormones, and growth factors. These processes involve genes regulating epithelial and endothelial interactions as well as temporal and spatial interactions of several hormones and growth factors.^{119,120} Hormones such as the glucocorticoids, thyroid hormone, and retinoic acid have been shown to regulate several of the crucial cellular interactions required for proper pulmonary organogenesis and differentiation. In the human embryo, respiratory tract development begins in the fourth week of gestation as a ventral out pouching of the foregut that soon has bifurcated and begun branching into the surrounding mesenchyme. The primitive, pluripotent epithelial cells differentiate into both bronchial and alveolar cell lines, under the control of the surrounding mesenchyme. By a process of asymmetric branching, the divisions are complete by the 16th week of gestation. Lung at this phase has columnar epithelium with thick mesenchyme giving rise to the descriptive term *pseudoglandular phase of development* because of its histologic appearance. The canalicular phase that follows and continues up to about the 24th gestational week is characterized by flattening of the epithelium of the distal airways, thinning of the mesenchyme, and the growth of the capillary network that surrounds the terminal airways. Gas exchange becomes functionally possible at the end of this phase. The terminal sac period that follows refers to the appearance of a thin respiratory epithelium in apposition to a capillary network capable of supporting gas exchange. True alveolar formation in humans begins shortly before or around the time of birth. Alveolar maturation and multiplication takes place after birth and may continue up to 8 years of age.

The precursors of the mesoderm-derived diaphragm begin to form during the fourth week of gestation with the appearance of the peritoneal folds from lateral mesenchymal tissue. At the same time, the septum transversum forms from the inferior portion of the pericardial cavity and serves to delineate the thoracic from the abdominal cavities. Eventually, the septum transversum leads to the formation of the central tendinous area of the fully developed diaphragm. The pleuroperitoneal folds extend from the lateral body wall and grow medially and ventrally until they fuse with the septum transversum and dorsal mesentery of the esophagus during the sixth gestational week. Complete closure of the canal takes place during the eighth week of gestation, with the right side closing before the left.¹²¹ Muscularization of the diaphragm appears to develop from the innermost layer of thoracic mesoderm, although other mechanisms have been proposed.¹²² A cell-based computer model system supports a pleuroperitoneal fold–dominated diaphragm morphogenesis theory in the rodent model, which creates a posteromedial diaphragm defect, whereas the posterolateral defect seen in humans would be supported by an alternate cellular development.¹²³ A contribution from cervically derived myoblasts is also present, as evidenced by the innervation of the diaphragm by the phrenic nerve originating from the third, fourth, and fifth cervical nerve roots. Posterolaterally, at the junction of the lumbar and costal muscle groups, the fibrous lumbocostal trigone remains as a

FIGURE 106.19. Anatomy of the diaphragm showing the location of congenital diaphragmatic defects.

small remnant of the pleuroperitoneal membrane and relies for its strength on the fusion of the two muscle groups in the final stages of development. It is in this area that the defect of CDH occurs (Fig. 106.19).

Congenital Diaphragmatic Hernia Pathology and Pathophysiology

The reported incidence of CDH is estimated to be between 1 in 2,000 and 1 in 5,000 births, making it one of the most common congenital abnormalities.¹²⁴ Approximately one third of infants with CDH are stillborn, but these deaths are usually due to associated fatal anomalies such as neural tube defects (anencephaly, myelomeningocele, hydrocephalus, and encephaloceles) and cardiac defects. Defects are more common on the left side (80% left, 20% right) based on the CDH registry.¹¹⁴ CDH is thought to represent a sporadic developmental anomaly, although a number of familial cases have been reported. The expected recurrence risk in a first-degree relative has been estimated to be 1 in 45.¹²⁴ One third of affected infants have associated major defects. The combination of CDH and an abnormal karyotype is associated with a poor outcome.¹²⁵ Associated significant heart disease is also a predictor of poor outcome.¹²⁶

The cause of CDH is unknown, but it is presumed that some combination of intrinsic predisposition (genetic factors) and environmental insult (teratogen or deficiency) results in abnormal diaphragm and lung development. Exposure to a number of pharmacologic agents has been implicated in its development, including certain drugs and insecticides such as phenmetrazine, thalidomide, quinine, and nitrofen.¹²⁴ Vitamin A deficiency in CDH infants and the effects of vitamin A administration in nitrofen-induced pulmonary hypoplasia have strengthened the evolving hypothesis that alterations in retinoid-regulated target genes may be responsible for CDH development.¹²⁷ Diaphragmatic hernia and pulmonary hypoplasia can be created in animal models, both surgically and pharmacologically.^{128–131} Genetically, there is currently no established inheritance pattern in patients afflicted with CDH.

During the early development of the diaphragm, the midgut is largely extracoelomic. If closure of the pleuroperitoneal canal has not occurred by the time the midgut returns to the

FIGURE 106.20. Autopsy specimen of an infant with severe pulmonary hypoplasia secondary to congenital diaphragmatic hernia. Pulmonary hypoplasia is bilateral, but the left lung is most severely affected.

abdomen during the 9th and 10th weeks of gestation, the abdominal viscera herniate through the lumbocostal trigone into the ipsilateral thoracic cavity. The resulting abnormal position of the bowel prevents its normal counterclockwise rotation and fixation. No hernia sac is present if the event occurs before complete closure of the pleuroperitoneal canal, but a nonmuscularized membrane forms a hernia sac in 10% to 15% of CDH patients. In addition to the small bowel, other intra-abdominal organs such as the spleen, stomach, colon, and liver may also herniate through the diaphragmatic defect.

12 Left-sided CDH is characterized by a 2- to 4-cm posterolateral defect in the diaphragm through which the abdominal viscera have translocated into the ipsilateral thoracic cavity. On a

right-sided defect, the large right lobe of the liver can occupy most of the hemithorax. The hepatic veins may drain ectopically into the right atrium, and the liver and lung may be fused.¹³²

The pathophysiology of CDH has been attributed to pulmonary parenchymal compression by the herniated organs and its effect on growth and maturation of the lung. An emerging school of thought attributes the pulmonary hypoplasia to an early mesenchymal developmental insult to the lung and diaphragm.^{119,120,133} Unilateral diaphragmatic hernia is associated with both ipsilateral and contralateral abnormal pulmonary development, although hypoplasia is more severe on the ipsilateral side. The lung on the side of the hernia is much smaller than its contralateral counterpart, and both are strikingly smaller than normal lungs (Fig. 106.20). The pulmonary vascular bed is abnormal in lungs from patients with CDH. There is a reduction in the total number of arterial branches in both the ipsilateral and contralateral pulmonary parenchyma. The small preacinar and intra-acinar arterioles feature inappropriate and significant medial muscular hyperplasia (Fig. 106.21). The physiologic consequence of this abnormal arteriolar muscularization may be an increased susceptibility to development of pulmonary hypertension.

Pulmonary blood flow accounts for only 7% of cardiac output during normal fetal development. Pulmonary vascular resistance is high. The fetus preferentially shunts oxygenated blood from the placenta through the foramen ovale and ductus arteriosus in a right to left direction into the systemic circulation. With the institution of breathing at birth, oxygen levels rise causing pulmonary vascular resistance to fall, which in turn allows an increase in pulmonary blood flow. Increased arterial oxygen tension then also induces spontaneous closure of the ductus arteriosus. Persistent fetal circulation may develop if this process is interrupted. Elevated pulmonary vascular resistance results in right to left shunting of blood at either the atrial or ductal levels with the delivery of unsaturated blood into the systemic circulation. As shunting increases, the oxygen saturation in the systemic circulation falls. The resulting hypoxia further increases pulmonary vascular resistance and compromises pulmonary blood flow while increasing the right to left shunt flow. Factors that contribute to the persistence of high pulmonary vascular resistance in CDH lungs are thought to be the structural changes of decreased total arteriolar cross-sectional area in the involved lungs and the increased muscularization of the arterial structures that are present. Additional exacerbations of pulmonary vascular resistance may be induced by the known stimulators of pulmonary hypertension, which include hypoxia, acidosis, hypothermia, and

FIGURE 106.21. Histology of pulmonary arteries. Pulmonary artery branches of similar size and location are shown in a normal infant (A) and in an infant with Bochdalek diaphragmatic hernia (B). There is increased muscle mass associated with the arterial wall in (B) (arrows). This vascular smooth muscle is exquisitely sensitive to chemical, hormonal, and paracrine mediators in the neonatal period. Pulmonary arterial vasospasm is an important cause of persistent fetal circulation and respiratory failure. Treatment of pulmonary hypertension is the primary objective in the immediate care of the newborn with congenital diaphragmatic hernia.

stress. Alterations in the levels of prostaglandins, leukotrienes, catecholamines, and the renin angiotensin system had been implicated as mediators of this complex process. The combination of hypoplastic lungs and lungs prone toward increased vascular resistance often proves to be deadly: A vicious cycle may ensue in which hypoplastic lungs and associated hypoxia leads to pulmonary hypertension in a lung vasculature already prone toward reactive vasospasm. The increase in pulmonary pressures results in a greater shunt, which in turn further reduces oxygen levels.

Diagnosis

The diagnosis of CDH is often made on a prenatal ultrasound examination, although studies have shown that up to 60% of

routine ultrasounds may fail to demonstrate a diaphragmatic hernia.¹³⁴ Polyhydramnios is common. Prenatal MRI evaluation is being now used routinely when obstetric sonography has detected a complex fetal anomaly and is ideally suited for fetuses with CDH.^{135,136} After birth, the spectrum of respiratory symptoms in an infant with CDH is determined by the degree of pulmonary hypoplasia and reactive pulmonary hypertension. Severely affected infants develop respiratory distress at birth, and most demonstrate respiratory symptoms within the first 24 hours of life. On physical examination, these infants have a scaphoid abdomen. A plain chest radiograph that demonstrates loops of intestines in the chest confirms the diagnosis of a CDH (Fig. 106.22). The location of the stomach is confirmed by placement of a nasogastric tube and may be predictive of survival.¹²⁵ The chest radiograph shows

FIGURE 106.22. A: Chest radiograph of a newborn with a left congenital diaphragmatic hernia. Mediastinal structures are shifted to the right. Abdominal viscera occupy the left hemithorax. The nasogastric tube locates the stomach. The child underwent repair of the congenital diaphragmatic hernia after treatment and resolution of pulmonary hypertension. B: Immediate postoperative photograph demonstrates return of mediastinal structures to a more normal position. The hypoplastic left lung is apparent. C: Chest x-ray 1 month later is unremarkable.

angulation of the mediastinum and a shifting of the cardiac silhouette into the contralateral thorax. Chest radiographs are unreliable for estimating the degree of pulmonary hypoplasia. Once the diagnosis of a CDH is confirmed, additional radiographic and ultrasonographic examination should be carried out to search for associated anomalies. Echocardiography should also be obtained. Diagnosis is made in 10% to 20% of infants after the first day of life. The diagnosis of a CDH can be confused with a number of other congenital thoracic conditions, including eventration of the diaphragm, anterior diaphragmatic hernia of Morgagni, congenital cystic disease of the pulmonary parenchyma, unilateral pulmonary effusion, and primary agenesis of the lung.¹³⁷

Prognostic Factors

Attempts to define clinically relevant prognostic factors to predict the outcome of infants with CDH have largely been unsuccessful. A prenatal anatomic parameter that appears to have predictive correlation is the determination of the lung to head ratio. The ratio is determined by multiplying the simultaneous sonographic measurements of size of the contralateral lung in an anteroposterior and lateromedial direction and dividing that multiple by the head circumference. Ratios less than 1.0 have been associated with poor outcomes.^{138–141} Anatomic factors such as the position of the stomach either above or below the diaphragmatic rim and the size of the diaphragmatic defect itself are also predictive of outcome. In fact, the CDH Registry suggests that the most powerful predictors of outcome are the presence of cardiac defects and the need for reconstruction of the diaphragm with a patch that serves as a surrogate for defect size.¹⁴² Physiologic parameters have been difficult to define and are limited to variations of arterial blood gas analyses, such as whether blood was obtained before or after treatment intervention and whether the blood was obtained preductal or postductal. MRI has allowed measurement of lung volume, which may be predictive of outcome.¹⁴³

Treatment

The fetus and mother should be referred to an appropriate tertiary perinatal center where the full array of respiratory care strategies including inhaled nitric oxide (iNO), oscillating ventilators, and ECMO are immediately available. Anything less may potentially compromise the best possible outcome. A spontaneous vaginal delivery is preferred unless obstetric issues supervene. CDH is a physiologic emergency and not a surgical emergency. The respiratory distress associated with a CDH in newborn infants results from a combination of uncorrectable pulmonary hypoplasia and potentially reversible pulmonary hypertension. The balance between these two factors determines the response to therapy and ultimately the outcome.

Resuscitation should begin with standard Neonatal Resuscitation Program guidelines and then proceed with endotracheal intubation and nasogastric tube insertion. Bag-mask ventilation is discouraged to avoid distention of the stomach and intestines that may be in the thoracic cavity. Meticulous attention must be paid to maintaining proper temperature regulation, glucose homeostasis, and volume status in the neonate. Systemic hypotension and inadequate tissue perfusion may be reversed with intravenous fluid administration including crystalloid, blood products, and colloid. Inotropic drugs such as dopamine or dobutamine may be required. Most infants can be successfully managed with a simple pressure-cycled ventilator with the goal of ventilatory support being a preductal p_aO_2 greater than 60 (S_aO_2 90% to 100%) with a corresponding p_aCO_2 of less than 60.^{144,145} The extremes of hyperventilation, particularly with high rates and high ventilatory pressures, should be avoided to prevent ventilator-

induced lung injury. If conventional mechanical ventilatory techniques cannot reverse the hypoxemia or hypercarbia, then high-frequency techniques using either the jet ventilator or the oscillating ventilator may be tried, although there are little data to suggest that these approaches are effective.

A broad spectrum of drugs and antihypertensive agents have been used in attempts to modify the pulmonary vascular resistance in infants with CDH and respiratory failure. Agents such as tolazoline (α -receptor blocker) have had marginal benefit in CDH infants. Other drugs, such as nitroprusside, isoproterenol, nitroglycerin, and captopril, have not been effective. The administration of various prostaglandin derivatives, including prostaglandin D_2 (PGD_2), prostaglandin 1 (PGE_1), and prostacyclin as well as the cyclo-oxygenase inhibitor indomethacin has also been disappointingly unsuccessful. Clinical and experimental studies have demonstrated surfactant deficiencies in infants with CDH. A multicenter review of surfactant administration in CDH patients showed no overall benefit to its use and demonstrated a lower survival rate in preterm infants compared to full-term infants.¹⁴⁶ At this time, there is no clinical data to support the administration of surfactant in the management of CDH infants. The combined administration of thyrotropin-releasing hormone and glucocorticoid therapy has been demonstrated to have positive effects on lung maturity.¹⁴⁷ However, a multicenter trial of prenatal steroid administration in fetuses with CDH failed to demonstrate enhanced lung function or survival.¹⁴⁸ Nitric oxide (NO) is a potent mediator of vasodilatation and particularly suited for administration to the pulmonary vasculature using inhalation techniques. It has been shown to be effective in improving oxygen saturation levels in neonates with respiratory failure due to prematurity and persistent pulmonary hypertension of the newborn. Unfortunately, its effects in CDH infants with respiratory failure have been disappointing. In fact, a multicenter trial of iNO in newborns with CDH suggested that the need for ECMO was increased in the iNO when compared to controls.¹⁴⁹ As a result, iNO should only be used as a temporizing measure in the deteriorating newborn with CDH.¹⁵⁰ Patients who do not respond to conventional treatments, HFOV, and NO are considered for ECMO treatment (see below).

Surgery

Multiple single-institution studies have reported improved survival rates with delayed surgery as part of their treatment protocols, while others have found no changes in overall outcome. No study has shown a decrease in survival rates with this technique.¹⁵¹ Although delayed surgical repair is now widely practiced, there is no statistical evidence that supports this approach over immediate repair.¹⁵² What the data does suggest, however, is that immediate repair does not show benefit over delayed repair.

The diaphragm defect is usually approached through a subcostal incision, although the repair can be performed through a thoracotomy incision (Fig. 106.23). Both thoracoscopic and laparoscopic techniques have been used to repair these defects, although the majority of surgeons tend to use a thoracoscopic approach because of the domain in the chest created by reducing the viscera into the abdomen.¹⁵³ Minimally invasive techniques may have a higher incidence of physiologic consequences in the newborn, specifically hypercarbia.¹⁵⁴ However, recent studies have demonstrated advances in the ability to close the larger defects that prevented minimally invasive repair of the diaphragm.¹⁵⁵ Once the abdominal contents are reduced, the defect in the diaphragm in the posterolateral position can be examined. In some patients, a hernia sac formed by parietal pleura and peritoneum is present and must be excised. Usually, there is an anterior rim of diaphragm of varying size, while the posterior rim must be exposed in the retroperitoneal

FIGURE 106.23. Repair of a congenital diaphragmatic hernia (CDH). **A:** Operative appearance of CDH. **B:** Placement of sutures for repair of a typical left posterolateral diaphragmatic defect. **C:** Completed repair. **D:** Prosthetic material may be used for large defects to avoid tension. (Adapted from Stollar CJH. Congenital diaphragmatic hernia. In: Spitz L, Coran AG, eds. *Rob and Smith's Operative Surgery: Pediatric Surgery*. 5th ed. London: Chapman and Hall; 1995.)

tissue. When diaphragmatic tissue is adequate, a primary repair with nonabsorbable suture material can be performed. If the defect is too large to be closed in a primary fashion, a number of reconstructive techniques have been described using rib structures and abdominal wall muscle flaps. The use of prosthetic material, such as Goretex, to complete the diaphragmatic closure has gained widespread acceptance. A floppy, tensionfree diaphragmatic repair can be accomplished that may lessen the degree of intra-abdominal pressure when closing the abdominal wall. The major drawback to using a prosthetic patch closure is the risk of infection as well as the risk of reherniation, which occurs in nearly 25% of patients with a patch repair. It has been suggested that the innervated latissimus dorsi muscle can be used to reconstruct the diaphragm in the setting of recurrence.¹⁵³ Tissue engineering may offer new materials for repair.¹⁵⁶

With the loss of intra-abdominal domain, abdominal wall closure may not be possible. In this situation, simple closure of the skin can be accomplished with prosthetic patch repair of the ventral wall. If increased abdominal pressures inhibit respiratory mechanics, a silo abdominal apparatus has been used effectively.¹⁵⁷ A tube thoracostomy may be placed, although

many surgeons find this unnecessary. The tube thoracostomy is of advantage in the nearly 30% of patients who develop chylothorax following diaphragmatic repair. The cause of frequent chylothorax is unclear and may require maintaining the patient as NPO (nothing by mouth), performance of pleurectomy, or ligation of the thoracic duct.¹⁵⁸

ECMO is a form of partial cardiopulmonary bypass with the goal of maintaining oxygen delivery to the body for an extended period of time when ventilator therapy has failed. It has become the cornerstone for managing infants who have life-threatening respiratory failure with CDH.¹⁵⁹ ECMO allows respiratory support without the risks of barotrauma and oxygen toxicity associated with conventional ventilation. Initially, infants were placed on ECMO after developing respiratory failure following the immediate repair of the diaphragmatic defect. With the evolution of delayed surgical repair, ECMO is now considered a part of the preoperative stabilization process. Failure to improve in the setting of severe pulmonary hypertension and progressive hypoxemia despite maximum medical intervention remains a valid qualifying criterion for ECMO support. As a result of the acceptance of delayed surgical repair as a treatment strategy, more than 90%

of CDH infants requiring ECMO support are placed on bypass before undergoing surgical repair.¹⁶⁰

Postoperative management should continue the goals established before surgery. Meticulous attention to fluid status must be maintained particularly in the immediate postoperative period. Weaning from ventilator support should be slow and deliberate as tolerated by the infant. Refractory postoperative pulmonary hypertension is relatively common in those who required ECMO and is often treated with iNO and prostacyclin (epoprostenol [Flolan]) in conjunction with frequent echocardiography to assess the effect of treatment. In those patients who are responsive to iNO, phosphodiesterase-5 inhibitors such as sildenafil may be used as a longer-term source of NO.¹⁶¹ A second course on ECMO may be employed with an expected survival of 47%.¹⁶²

Outcome

Survival rates (discharge to home) for infants born with an isolated CDH have improved dramatically over the past decade when compared to the historical values of approximately 50%. The CDH Registry suggests that overall mean survival rates of 67% are being observed with current treatment modalities.¹⁶³ Resolution of pulmonary hypertension is predictive of survival.¹⁶⁴ Long-term studies have shown that many surviving infants will have normal pulmonary function measurements, including total lung capacity, vital capacity, and carbon monoxide diffusing capacity. Even studies following patients into adulthood demonstrate minimal lung compromise.¹⁶⁵ In the last decade, as survival rates have improved, a new group of survivors is emerging with different patterns of long-term morbidities.¹⁶⁶ Chronic lung disease has been reported in CDH survivors, particularly in those requiring ECMO.¹⁶⁷ Long-term problems that have been identified with increasing frequency include chronic lung disease, neurologic abnormalities with developmental delay, skeletal deformities, and nutritional and growth-related problems.

Evolving Therapies

Even with the increasing success of current treatment strategies such as permissive hypercapnea, delayed surgery, antihypertensive pharmacology, and advanced ventilatory techniques, a cohort of infants refractory to these interventions continue to be candidates for novel treatments.

In Utero Repair of Diaphragmatic Hernia. The concept of fetal surgical intervention evolved from the experimental observation in lambs that reduction of compressive forces on the lung resulted in continued pulmonary growth and development.¹⁶⁸ Although technically and theoretically exciting, the clinical results have been disappointing.^{169,170} A direct advancement of these initial attempts at in utero repair was the observation that fetal tracheal ligation accelerated fetal lung growth and reversed pulmonary hypoplasia.^{171,172} Tracheal occlusion or PLUG therapy (plug the lung until it grows) resulted in improved oxygenation and ventilation after birth when compared to untreated control animals.¹⁷³ A randomized clinical trial comparing fetal endoscopic tracheal occlusion to current standard postnatal care for severe CDH showed no benefit in survival.¹⁷⁴ Early-onset labor was a major problem for both trials studying in utero CDH repair and in utero tracheal ligation. In fact, the early delivery of fetuses in the treatment arm may have masked evidence of benefit for either approach. European centers have been applying transuterine fetal bronchoscopy at 26 weeks gestation with balloon tracheal ligation followed by removal of the balloon at 34 weeks. This minimally invasive approach has decreased the incidence of early delivery and has been used extensively with

promising results.¹⁷⁵ Multicenter trials of this technique are being considered.

Liquid Ventilation and Perfluorocarbon-induced Lung Growth. Liquid ventilation using perfluorocarbons has now advanced to the point of clinical applicability.¹⁷⁶ Partial liquid ventilation has been attempted in a small number of CDH infants while on ECMO. Improvements in oxygenation levels and pulmonary function tests were noted. Perfluorocarbon-induced lung growth provides a unique approach to the problem of lung hypoplasia in newborns with CDH. The lungs are filled with perfluorocarbon and continuous positive airway pressures of 5 to 8 cm of H₂O are applied, which appears to lead to lung growth and enhanced gas exchange.¹⁷⁷ A prospective controlled study is being performed to assess the effectiveness of this technique.

Pulmonary Transplantation. Successful neonatal lung transplantation for CDH has been achieved in a few patients, but the experience is too small at this time to recommend this form of treatment. Most interesting is one patient with CDH who underwent single lung transplant as an infant at Stanford University and who, as a child, had the biologic graft removed once native lung function was adequate.¹⁷⁸

Foramen of Morgagni Hernia

The anterior diaphragmatic hernia of Morgagni is located anteromedially on either side of the junction of the septum transversum and the thoracic wall. Typically, a sac is present, and herniation of the colon, small bowel, or liver is usually discovered to the right or left of the midline. Morgagni hernias account for less than 2% of diaphragmatic defects and usually present in older children or adults. The hernia is often discovered incidentally as a mass or air fluid level on chest radiograph. Because of the risk of segmental intestinal volvulus or obstruction, surgical repair of the defect is recommended. Operative correction may be performed via a laparoscopic approach. The diaphragm is sutured to the undersurface of the posterior rectus sheath at the costal margin.

Eventration of the Diaphragm

Eventration of the diaphragm may be either congenital or acquired. The congenital form may be indistinguishable from a diaphragmatic hernia with a sac, and symptoms are similar, although the presentation is typically clinically less severe. The acquired form is due to paralysis of the phrenic nerve. The phrenic nerve is vulnerable to surgical trauma from a wide variety of cervical, thoracic, and diaphragmatic procedures. Phrenic nerve injuries and a variety of neuromuscular disorders including primary myopathies and degenerative diseases may produce diaphragmatic paralysis and require operative plication of the diaphragm in infants and young children. The most common cause of phrenic nerve injury in children is associated with thoracic and mediastinal surgery. Cervical stretching at birth may result in phrenic nerve injury. The diaphragmatic muscle is usually present in its normal distribution but is attenuated and nonfunctional. When an acquired nerve palsy is present, initial treatment may be expectant.

An eventration may be completely asymptomatic and noted only on chest x-ray. Clinical findings may range from mild respiratory compromise with wheezing, frequent respiratory infections, and exercise intolerance to extreme respiratory distress. Diagnosis is usually made by fluoroscopic examination of the chest with examination of diaphragmatic motion. In such cases, the diaphragm moves paradoxically with respiration. A small or asymptomatic eventration may be left untreated and observed. It has been postulated that an eventration that

involves a large area of the diaphragm may adversely affect pulmonary function and lung growth and should be repaired. However, there are no long-term data assessing the effect of an asymptomatic, high-riding diaphragm on future lung function. Under most circumstances where the respiratory status of the infant remains compromised, surgical intervention should be considered. Repair may be either through the abdomen or the chest, but in most cases a thoracoscopic approach is preferred.¹⁷⁹ The diaphragm is plicated with nonabsorbable sutures placed in an anteroposterior orientation. The redundant diaphragmatic tissue is reefed up until it is taut.

Diaphragm Pacing

Ventilator-dependent children with spinal cord injury or central hypoventilation syndromes may benefit from diaphragm pacing.¹⁸⁰ The application of repetitive stimulus patterns to the phrenic nerves causes rhythmic contractions of the diaphragm. Phrenic nerve pacing wires are implanted at the cervical or intrathoracic level. Receivers are implanted in subcutaneous pockets, while an external microprocessor-controlled transmitter/antenna assembly activates the receiver. Patients with injured phrenic nerves (high spinal cord injury) may benefit from diaphragm pacing after intercostal to phrenic nerve transfer.¹⁸¹

PLEURAL DISEASES

Empyema

Empyema is an accumulation of purulent material within the pleural space. In children, empyema occurs most often as a sequelae of bacterial pneumonia. Empyema develops when a parapneumonic effusion becomes infected or necrotizing pneumonia erodes through the lung into the pleural space. Empyema may also develop after penetrating thoracic trauma, intrathoracic or cervical esophageal perforation, or surgery on the chest. Empyema is divided into three stages:

- **Exudative:** Thin free-flowing fluid with a low cell count
- **Fibrinopurulent:** Thick purulent material resulting in multiple loculations and encasement of the lung parenchyma
- **Organizing:** Fibroblasts that have grown into the exudate and have produced a fibrotic peel

Haemophilus influenzae, *Streptococcus pneumoniae*, and *Staphylococcus aureus* are the most common pathogens in pediatric pneumonia, with anaerobes, gram-negative bacteria, and atypical organisms also being occasionally found. The signs and symptoms of an empyema in a child are usually those of worsening pneumonia with fever, tachypnea, shortness of breath, and sometimes cyanosis. Abdominal pain with distention and ileus may intensify the respiratory difficulty.

Diagnosis is confirmed by the presence of pleural fluid and loculation on conventional chest radiographs (Fig. 106.24A). CT scan of the chest cavity is the best method of determining the extent of loculated effusion and underlying parenchymal involvement (Fig. 106.24B).

When a small parapneumonic effusion develops, it may resolve with antibiotics alone. Larger effusions will require adequate pleural space drainage with a tube thoracostomy in addition to antibiotic therapy. It is reasonable to place the thoracostomy tube in the operating room and, at the same time, perform thoracoscopic decortication/pneumolysis and pleural debridement along with evacuation of loculated pleural fluid. This video-assisted thoracoscopic surgery (VATS) approach has proven to be very effective in the treatment of pediatric empyema, shortening hospitalization and resulting in more rapid recovery^{182,183} (Fig. 106.24C,D).

Instillation of intrapleural streptokinase or urokinase also has been utilized for loculated effusions. In fact, a randomized controlled study of VATS versus tissue plasminogen activator therapy with thoracostomy tube drainage demonstrated a reduction in cost with tissue plasminogen activator treatment with equivalent efficacy.¹⁸⁴

Pneumothorax

Spontaneous pneumothorax is seen in previously healthy older children and teenagers who are usually tall and thin. They often have apical blebs seen on chest radiographs. CT scanning is more sensitive to detect bleb disease, but is not necessary prior to operation. Pneumothorax may also complicate advanced pulmonary disease due to cystic fibrosis. Other causes include both blunt and penetrating thoracic trauma, severe asthmatic attack, or pulmonary infection. The classic presentation of a spontaneous pneumothorax is the sudden onset of chest pain and shortness of breath.

Diagnosis is best confirmed by chest radiograph. In patients with significant symptoms, tube thoracostomy should be immediately performed and the chest tube placed to water seal suction drainage.

Recurrent pneumothoraces can be treated nonoperatively with the intrapleural instillation of various sclerosing agents such as talc or tetracycline through the chest tube. Patients with recurrent pneumothorax and apical blebs are treated with bleb removal and pleurodesis. The blebs will be found at the apex of the upper lobe or at the apex of the superior segment of the lower lobe. Excision of the blebs and pleurodesis may be performed through a VATS approach.¹⁸⁵

Chylothorax

In the newborn, chylothorax may occur in association with manipulation during a difficult delivery as a result of congenital diaphragmatic hernia repair, from a malformation of the thoracic duct, or spontaneously without an obvious cause. In older infants and children, cardiothoracic procedures can be complicated by postoperative chylothorax in 0.5% of the cases. The thoracic duct has also been known to rupture during violent bouts of coughing or with hyperextension of the spine. Obstruction or erosion of the duct may occur as a result of malignant disease within the mediastinum such as lymphoma. Other causes include inflammatory processes, subclavian vein or superior vena caval thrombosis, and misplaced central venous devices.

A defect in the lower portion of the duct frequently results in an effusion into the right pleural space, while an effusion on the left results from a defect in the upper region of the duct. Clinically, the patient presents with a large pleural effusion resulting in pulmonary compression, mediastinal displacement, and the progressive development of respiratory distress. Radiographs will generally show a massive effusion on the involved side. The diagnosis should be suspected at the initial thoracentesis with the retrieval of milky, lipid-laden fluid. Laboratory values will confirm a chylothorax if a pleural fluid cell count differential is greater than 90% lymphocytes, which is the primary means of diagnosis in patients who are not being fed.

Initial treatment consists of tube thoracostomy for evacuation of the chylous fluid and expansion of the collapsed lung. Minimizing the flow of lymph within the thoracic duct by placing the patient on complete bowel rest using parenteral nutrition has been shown to permit healing of the thoracic duct lymph fistula over time. With newborns, spontaneous chylothorax usually ceases spontaneously with adequate drainage. If the chylothorax persists, fluid and protein losses may complicate the management of the newborn with chylothorax and predispose the patient to sepsis. As such, if no

FIGURE 106.24. Video-assisted thoracoscopic treatment of complicated empyema in children. **A:** Chest radiograph of a 2-year-old child presenting with pneumonia and pleural effusion. **B:** Computerized tomography demonstrates complicated pneumonia with loculated empyema. **C:** Video endoscopic view of organized empyema debris. **D:** “Decortication” procedure includes removal of all loculated, organized debris from the hemithorax. All surfaces of the visceral and parietal pleura are accessible using video endoscopic techniques. **E:** Immediate postoperative chest x-ray shows the expected residual parenchymal lung disease. **F:** One month later, the chest radiograph findings have resolved.

improvement is noted after a brief period of conservative therapy, then surgical intervention should be considered. Through either an open thoracotomy or with video-assisted thoracoscopy, the surgical therapy involves ligation of the thoracic duct just above the diaphragm within the right chest. This goal can be accomplished with surgical ligation, direct clipping, the use of fibrin glue, and pleurodesis. Administration of cream via a nasogastric tube in the hours prior to operation may make identification of the thoracic duct and an associated leak more obvious. For intractable conditions, unilateral or bilateral pleurectomy may be effective. Pleural peritoneal shunting can also be considered. Octreotide is of questionable value in the treatment of postoperative chylothorax.¹⁸⁶

CHAPTER 107 ■ PEDIATRIC ABDOMEN

THOMAS T. SATO AND KEITH T. OLDHAM

KEY POINTS

- 1 Gastroschisis occurs with an incidence rate of 1 in 3,000 to 8,000 live births and is characterized by exposed intestine herniating through a defect to the right of the umbilicus. In contrast, omphalocele is an abdominal wall defect of varying size characterized by herniated visceral contents contained in a sac, and has a high incidence rate of associated congenital anomalies.
- 2 A congenital, indirect inguinal hernia is an abnormal, patent continuation of the peritoneum through the internal inguinal ring; inguinal hernia repair is the most common elective procedure in pediatric surgery.
- 3 Neonatal bilious emesis should be considered the result of an acute mechanical intestinal obstruction until proven otherwise; emergent surgical evaluation is warranted to determine if intestinal malrotation with midgut volvulus is present.
- 4 Necrotizing enterocolitis (NEC) is a progressive, inflammatory intestinal condition of the surviving premature neonate. Perforated NEC is the most common neonatal surgical emergency.
- 5 Hirschsprung disease is caused by aganglionosis of the myenteric nervous system in the rectum, and it will involve the contiguous bowel for varying lengths proximally, most commonly to the rectosigmoid colon. Both propulsion and reflexive relaxation is disordered or absent in the rectum, leading to functional bowel obstruction in the neonate and chronic constipation in the older child or adolescent. Enterocolitis associated with Hirschsprung disease is a potentially life-threatening condition.
- 6 Intussusception is the invagination or telescoping of a proximal segment of intestine into an adjacent distal segment and is the most common cause of intestinal obstruction in infants and children 3 months to 3 years of age.
- 7 The incidence of biliary atresia is 1 in 8,000 to 12,000 live births and is the most common cause of chronic cholestasis in infants and children as well as the most frequent indication for pediatric liver transplantation. Early diagnosis and management is necessary for optimal outcome.

ABDOMINAL WALL DEFECTS

Gastroschisis

- 1 Gastroschisis occurs with an incidence rate of 1 in 3,000 to 8,000 live births, and for unknown reasons, the incidence rate is increasing. Infants with gastroschisis tend to be born prematurely, have lower birth weights, and have younger mothers.^{1,2} Familial cases of gastroschisis have been reported and are distinctly rare.³ Associated congenital anomalies are uncommon and occur in about 10% of cases, most commonly intestinal atresia or stenosis. These anomalies are thought to reflect mechanical or vascular compromise to the herniated bowel. Rarely, infants with gastroschisis have complete loss of small bowel secondary to in utero volvulus.

The pathophysiology of gastroschisis remains unknown. In normal fetal development, there are two paired umbilical veins. As the intestine returns to the abdominal cavity through the umbilicus, the right umbilical vein undergoes resorption, leaving the left umbilical vein intact. Weakness of the umbilical membrane at the site of umbilical vein resorption may allow for evisceration of the intestine through the defect. This explanation is consistent with the clinical observation that the gastroschisis defect is almost always located to the right of the umbilicus. Routine antenatal ultrasonography has documented the sequential development of gastroschisis as a consequence of a ruptured hernia of the umbilical cord in utero.⁴ Therefore, gastroschisis should be considered an isolated mechanical defect of the developing umbilical cord rather than a global defect in embryogenesis.

The amount of bowel eviscerated in gastroschisis can be extensive because the bowel has not undergone complete mesenteric rotation and fixation. Typically, the bowel is thickened and the mesentery may be foreshortened secondary to the

inflammatory response induced by direct exposure to amniotic fluid. Given the typical small size of the abdominal wall defect, herniation of the liver in gastroschisis is distinctly unusual (Fig. 107.1).

Omphalocele

Anatomy, Embryology, and Pathophysiology. The incidence rate of omphalocele is approximately 1 in 6,000 to 10,000 live births and has been stable over the past several decades. *Omphalocele* is an abdominal wall defect of varying size characterized by the presence of herniated visceral contents into a translucent sac. The sac is composed of amniotic membrane, mesenchymal tissue known as *Wharton jelly*, and peritoneum. The umbilical cord attaches to the sac and may be eccentric in origin (Fig. 107.2). The sac may be inadvertently ruptured before or during delivery, but it is always present. As in gastroschisis, intestinal malrotation is usually present. Unlike in gastroschisis, the bowel is normal in appearance because it has not been directly exposed to the amniotic fluid. Small omphaloceles are abdominal wall defects 2 to 5 cm in diameter and may have only a small amount of herniated bowel within the sac. Giant omphaloceles greater than 8 cm in diameter can lead to extensive herniation of the stomach, bowel, liver, and spleen with subsequent underdevelopment of the abdominal cavity (Fig. 107.3).

Omphalocele results from incomplete closure of the anterior abdominal wall at the umbilicus during embryogenesis. During week 4 of gestation, the midgut undergoes progressive elongation in the yolk sac outside the embryonic coelomic cavity. The midgut returns to the abdominal cavity during week 10, where it undergoes normal rotation and fixation of the mesentery to the posterior abdominal wall. Normal closure of

FIGURE 107.1. Gastroschisis. The defect is to the right of the normal umbilicus, and the bowel is thickened and inflamed.

FIGURE 107.3. Ruptured omphalocele. Although the bowel is relatively normal in appearance, the abdominal cavity is extremely underdeveloped.

the anterior abdominal wall requires return of the midgut to the abdominal cavity, along with growth and fusion of the anterior body folds (cephalic, caudal, and two lateral) at the base of the umbilicus. Failure of growth, migration, or fusion of the lateral body folds leads to omphalocele. Failure of growth and fusion of the cephalic folds may lead to either a supraumbilical omphalocele associated with a midline sternal defect (Fig. 107.4) and a herniated heart, termed *ectopia cordis*, or a constellation of defects known as the *pentalogy of Cantrell*.⁵ This sequence includes a sternal cleft, an absence of the septum transversum of the diaphragm, a pericardial defect, a cardiac defect, and an epigastric omphalocele. Infants born with either *ectopia cordis* or pentalogy of Cantrell have significant morbidity, and often these conditions are lethal.

Associated anomalies are more common in infants with omphalocele than with gastroschisis, reflecting the more global abnormality of embryogenesis in omphalocele. About 50% to 60% of infants with omphalocele have at least one associated congenital anomaly.^{6,7} These infants are at moderate to high risk for anomalies of the skeleton, gastrointestinal tract, nervous system, genitourinary system, and cardiopulmonary system. In addition, infants with omphalocele have a higher incidence of chromosomal abnormalities and other conditions such as Beckwith-Wiedemann syndrome. A comparison of gastroschisis and omphalocele is summarized in Table 107.1.

FIGURE 107.2. Omphalocele. The herniated intestines and liver are visible inside the sac. The umbilical cord attaches to the sac.

FIGURE 107.4. Operative exploration of giant omphalocele with abdominal wall defect, absence of the septum transversum of the diaphragm, and pericardial defect, cardiac defect.

Perioperative Management for Gastroschisis and Omphalocele.

In the absence of fetal distress, whether elective cesarean section improves neonatal outcome in infants with gastroschisis or omphalocele remains controversial.^{8–10} Some investigators advocate elective delivery of infants with gastroschisis following the establishment of lung maturity. A prospective study that alternated vaginal delivery with elective cesarean section for infants with gastroschisis demonstrated no significant differences in outcome.¹¹ To prevent birth-related hepatic injury, cesarean section is preferable for prenatally diagnosed infants with giant omphaloceles.

After delivery, infants with either gastroschisis or omphalocele have similar initial management priorities. Attention must be given to the establishment of an adequate airway with effective ventilation and oxygenation. The infant should be maintained under either an external warmer or a humidified incubator. An orogastric sump tube should be inserted early and placed on suction to prevent further intestinal distention. The herniated viscera should be covered with warm, saline-soaked gauze and covered with plastic wrap to prevent further contamination; this maneuver also helps to prevent hypothermia and volume depletion. Alternatively, the infant's entire lower torso can be placed inside a plastic bowel bag. Regardless of the method, the initial therapeutic goal is to provide rapid, effective temporary coverage of the viscera. Adequate support of the herniated viscera must be provided to prevent intestinal

TABLE 107.1**DIAGNOSIS****COMPARISON OF GASTROSCHISIS AND OMPHALOCELE**

■ CHARACTERISTIC	■ GASTROSCHISIS	■ OMPHALOCELE
Defect size (diameter)	2–3 cm	2–15 cm
Sac	Never	Always, may be ruptured
Gestational age	Prematurity	Term
Umbilical cord	Adjacent (left side) of defect	Attached to sac
Herniated viscera	Small bowel, stomach, colon	Small bowel, stomach, colon, liver
Malrotation	Yes	Yes
Bowel character	Inflammatory, edematous	Normal
Enteral nutrition	Delayed	Normal
Associated anomalies	Uncommon (10% atresia)	Common (50%)

ischemia. With large omphaloceles, the position of the infant's liver and viscera may impair venous return from the inferior vena cava when the infant is supine, and these infants may preferentially require a left-side-down position to maintain normal hemodynamic status. Intravenous dextrose and broad-spectrum antibiotics are administered. Given the inflammatory nature of the intestine, infants with gastroschisis will have higher intravenous fluid requirements to maintain euvolemia. If the infant is not delivered at a center where definitive surgical care can be provided, urgent transport should be arranged.

Given the high incidence of associated anomalies, infants with an intact omphalocele should undergo preoperative diagnostic investigation, guided by the clinical presentation and physical examination of the infant. These studies include a chest film, echocardiogram, and renal ultrasound, in addition to baseline blood work. Until the decision is made with respect to the timing and method of repair, the omphalocele should remain covered and protected with a dressing. If the omphalocele is ruptured or torn, immediate closure or coverage is necessary.

Once the infant has been stabilized and assessment for other anomalies is complete, the infant is taken to the operating room for correction of the abdominal wall defect. Reduction of the herniated viscera with primary fascial closure of the abdominal wall is an achievable goal in approximately 60% to 70% of infants with either gastroschisis or omphalocele. Gentle but definitive stretching of the abdominal wall is performed, and proximal decompression of the bowel is maintained with orogastric decompression. The defect may require enlargement to evaluate fully the intestinal tract. With omphalocele, the sac is usually resected. The limiting factor in primary closure of a congenital abdominal wall defect is the increased intra-abdominal pressure generated by the reduction of the herniated viscera. Increased intra-abdominal pressure can lead to abdominal compartment syndrome. Features of neonatal abdominal compartment syndrome include impaired venous return caused by compression of the inferior vena cava, reduction of splanchnic blood flow leading to mesenteric ischemia, and respiratory compromise secondary to impaired diaphragmatic excursion. Intraoperative measurement of intragastric or intravesical pressure, end-tidal CO₂, central venous pressure, or regional oximetry may be helpful in determining the safety of primary abdominal wall closure.¹² If the herniated viscera cannot be reduced primarily, a silicone elastomer pouch or silo is constructed and daily partial reduction of the silo is performed. This technique allows more gradual reduction of the herniated viscera into the abdominal cavity, and complete reduction usually is obtained within 3 to 7 days. The infant is returned to the operating room for removal of the temporary silo with delayed primary closure of the abdominal wall defect (Fig. 107.5).

Staged closure of gastroschisis using commercially available silicone elastomer silos has been reported to decrease the risk of long-term bowel dysfunction and need for reoperation by avoiding abdominal compartment syndrome.¹³ Alternatively, a large abdominal wall defect may be effectively covered with abdominal skin flaps with delayed repair of the ventral hernia months to years later.

Infants with intact, giant omphaloceles may also be managed nonoperatively. The sac can be physically supported and left undisturbed, allowing epithelialization of the sac over several weeks to months. Antibiotic solutions or ointments are usually applied to control desiccation. Delayed repair of the ventral hernia is required. This delay is particularly useful in the infant with a giant omphalocele and a small, underdeveloped abdominal cavity that prohibits primary closure.

Infants with repaired omphalocele usually have relatively prompt return of bowel function after definitive repair. In comparison, nearly all infants with gastroschisis have delayed intestinal function following closure. The use of total parenteral nutrition (TPN) is essential in the treatment of these infants because it allows nutritional support while the bowel inflammatory process resolves. It is not unusual for these infants to require up to 4 weeks after repair to have bowel function normalize, and time taken to achieve full enteral feeding is not affected by the use of erythromycin as a prokinetic agent.¹⁴ Approximately 15% of infants with gastroschisis develop necrotizing enterocolitis (NEC), a diffuse, often life-threatening

FIGURE 107.5. Silastic chimney or silo for temporary coverage and staged reduction of giant omphalocele.

inflammatory complication of the neonatal intestinal tract.¹⁵ In addition, infants with gastroschisis are at risk for nutrient malabsorption and intestinal dysmotility with inability to tolerate full enteral feeding. In particular, infants with gastroschisis and associated intestinal atresia may have pronounced intestinal dysmotility and may require long-term, sometimes lifelong, dependence on TPN for caloric intake.¹⁶

Long-term outcome of infants operated on for gastroschisis or omphalocele is usually dependent on the morbidity and mortality of associated conditions rather than the abdominal wall defect itself. Surgical conditions such as undescended testicles, Meckel diverticulum, and adhesive small bowel obstruction are encountered with moderate frequency. Adhesive small bowel obstruction most commonly occurs in the first year of life and requires operative management in most.¹⁷ Most children with repaired abdominal wall defects enjoy satisfactory health and quality of life, although they have been reported to have a lower degree of physical fitness measured by exercise time and maximal oxygen consumption.¹⁸

Umbilical Hernia

Anatomy and Embryology. Congenital umbilical hernia is the most common abdominal wall defect in infants and children. The umbilical ring begins to contract circumferentially after birth and normally is reinforced by the paired lateral umbilical ligaments (the obliterated umbilical arteries), the singular round ligament (the obliterated umbilical vein), the urachal remnant, and the transversalis fascia. Incomplete growth or impaired development of any one of these structures can lead to weakness at the umbilical ring and cause a congenital umbilical hernia.

Clinical Issues and Management. Congenital umbilical hernias generally do not pose significant problems during childhood. Rarely, an umbilical hernia presents with incarceration of intra-abdominal contents within the sac.¹⁹ Infants and children may also present with infection or drainage at the umbilicus from associated urachal or vitelline duct remnants. The incidence rate of congenital umbilical hernia has been reported to be 25% to 50% in black infants and 4% to 9% in white infants in the first few months of life.²⁰ There is an increased incidence of umbilical hernia in premature infants, and there is a tendency for familial inheritance.

Diagnosis of umbilical hernia is usually made after separation of the umbilical cord remnant from the umbilicus and is often initially noted by parents or pediatrician. The defect size may vary from a few millimeters to several centimeters and is typically reducible and asymptomatic. Age and size of the defect are the most important factors determining spontaneous closure rates.²¹ Many umbilical hernias spontaneously close within the first 2 to 3 years of life. Parents should be reassured that complications related to untreated umbilical hernia are rare. Given the high rate of spontaneous closure and the relatively asymptomatic nature of most umbilical hernias, operative repair is generally not performed during the first 2 years of life. Skin ulceration or an episode of incarceration should prompt earlier repair. Large defects with significant protrusion may necessitate surgery, and parents may desire repair if an older child appears to be self-conscious about the hernia.

Nearly all umbilical hernia repairs can be performed as outpatient surgical procedures. An incision is made along the umbilicus and the hernia sac is dissected free circumferentially. The sac is completely excised and primary fascial closure is performed. The umbilical skin is typically preserved and sutured to the fascial closure, and an acceptable cosmetic result is almost always achievable. Large umbilical hernias with redundant skin may require umbilicoplasty. The incidence of complications such as wound infection and recurrence is low.

Inguinal Hernia and Hydrocele

Anatomy, Embryology, and Pathophysiology. Inguinal hernias constitute one of the major surgical problems of infancy and childhood. Inguinal hernia repair is the most common elective general surgical procedure performed by pediatric surgeons. Three distinct anatomic types of inguinal hernias are observed in children: congenital indirect (99% of infants and children), direct (0.5%), and femoral (<0.5%). An *indirect inguinal hernia* is an abnormal, patent continuation of the peritoneum through the internal inguinal ring. The hernia sac originates lateral to the deep inferior epigastric vessels and descends along the spermatic cord within the cremasteric fascia. The sac can reside completely within the inguinal canal or descend through the external inguinal ring into the scrotum. A *direct inguinal hernia* originates medial to the deep inferior epigastric vessels and is external to the cremasteric fascia. The hernia sac protrudes directly through the posterior wall of the inguinal canal and can descend through the external inguinal ring and into the scrotum. A *femoral hernia* originates medial to the femoral vein and descends inferior to the inguinal ligament along the femoral canal. A femoral hernia never enters the scrotum or labia.

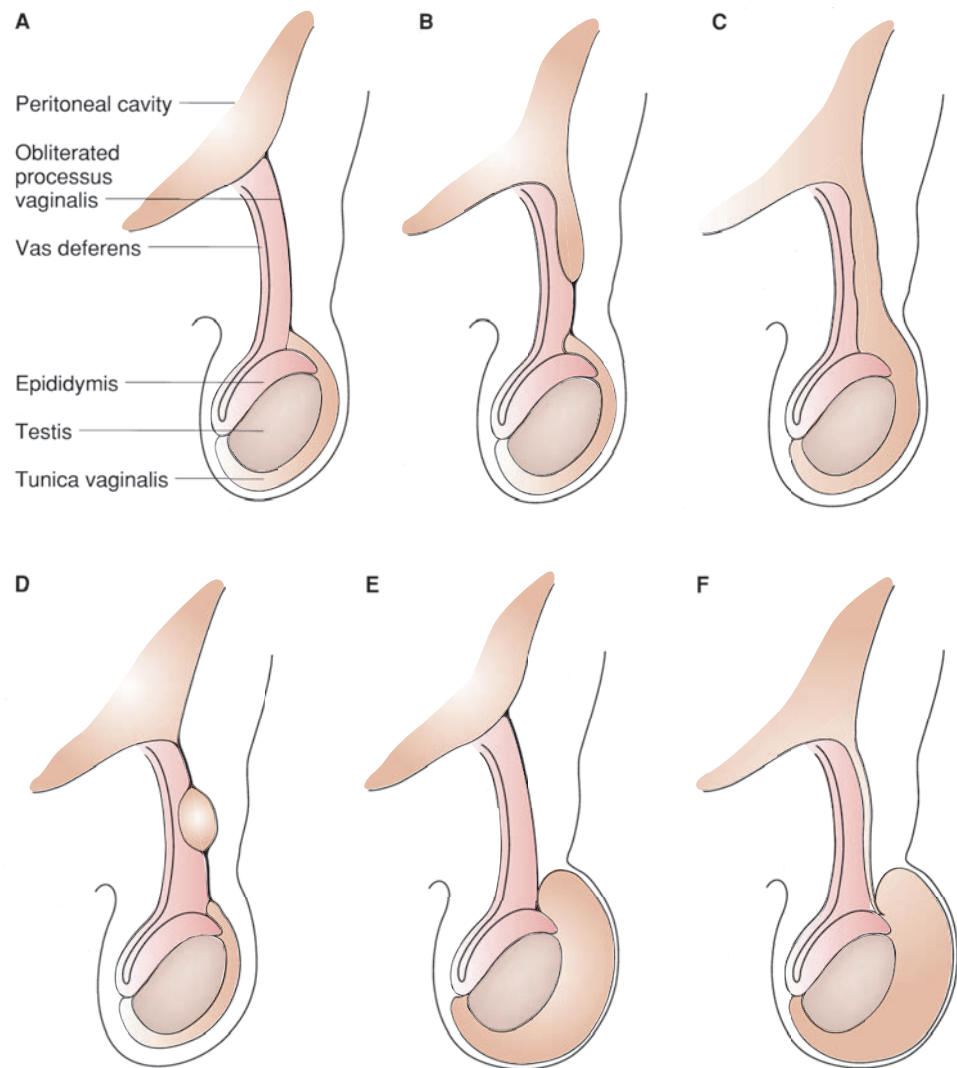

The developing testicle is initially adjacent to the mesonephros and subsequently descends to the scrotum during the third trimester of gestation. The peritoneal extension that descends alongside the chorda gubernaculum of the testicle is called the processus vaginalis. A slightly higher incidence rate of right-sided indirect inguinal hernia is thought to reflect delay of right-sided testicular descent from the developing inferior vena cava and right external iliac vein. As the testicle descends into the scrotum, the processus vaginalis forms a serous covering around the testicle known as the tunica vaginalis. Normally, the patent processus vaginalis undergoes obliteration, closing the communication between the peritoneal cavity and the inguinal canal. A patent processus vaginalis can lead to various anatomic conditions of the inguinal region (Fig. 107.6).

The incidence of patent processus vaginalis has been reported to be as high as 80% to 94% in newborn infants undergoing autopsy,²² whereas in adulthood, the incidence is 20% to 30%. Infants with unilateral inguinal hernias have been found to have a patent contralateral processus vaginalis in 60% during the first few months of life. By the age of 2 years, 20% of these hernias were obliterated, and half of the remaining 40% became clinical hernias.²³ At least 30% of infants requiring placement of a ventriculoperitoneal shunt for hydrocephalus have been observed to have a patent processus vaginalis in the first few months of life, with a rapid decline in patency in older children.²⁴ These studies, along with contemporary use of laparoscopic exploration of the contralateral internal ring, demonstrate that although a patent processus vaginalis is common in infancy, there is some degree of obliteration that occurs with increasing age, and a patent processus vaginalis by itself does not constitute a clinical inguinal hernia.

Clinical Issues. Inguinal hernias occur in 1% to 3% of all children and in 3% to 5% of premature infants. There is no known inheritance pattern, but there is an increased incidence of inguinal hernia in children with connective tissue disorders such as Ehlers-Danlos syndrome and Marfan syndrome. There is a 6:1 predominance of males to females. At least 30% of children are younger than 6 months of age at the time of operative repair. Inguinal hernia more commonly presents as right-sided (56.2%) compared with left-sided (27.5%) or bilateral (16.2%).²⁵

Most infants and children have a history of an intermittent inguinal mass or bulge that may descend into the scrotum or labia. The hernia may become more pronounced during times of increased intra-abdominal pressure, such as crying or having a bowel movement. Most inguinal hernias in children reduce

FIGURE 107.6. Anatomic variations that occur with different degrees of obliteration of the processus vaginalis. **A:** Normal; obliterated processus vaginalis. **B:** Proximal hernia sac; distal obliterated processus. **C:** Hernia sac extending into scrotum; no obliteration. **D:** Proximal and distal obliteration with hydrocele of the cord. **E:** Hydrocele of the scrotum, obliterated processus. **F:** Patent processus with communicating hydrocele.

spontaneously or are reducible with gentle, manual pressure along the inguinal canal. Female infants may have an ovary and fallopian tube in the hernia sac, identified clinically as a firm, slightly mobile, nontender mass in the labia or inguinal canal. Most parents or pediatricians give a characteristic history that is sufficient to warrant inguinal exploration, even in children in whom the hernia cannot be clinically demonstrated at the time of examination. Depending on institution and surgeon preference, infants and children with a strong history consistent with inguinal hernia and an equivocal clinical examination may be offered ultrasound or diagnostic laparoscopy to effectively confirm the diagnosis before groin exploration.²⁶

Incarceration is a common consequence of untreated inguinal hernia and presents as a nonreducible mass in the inguinal canal, scrotum, or labia.²⁷ Clinical symptoms and signs are related to the duration of incarceration. If the incarceration has been present for several hours, the infant may be inconsolable and have feeding intolerance, pain, abdominal distention, vomiting, and lack of flatus or stool, signaling complete intestinal obstruction. The affected groin may become quite edematous, and a reactive scrotal hydrocele may evolve. Elevation of the infant's lower extremities with a pillow may help to encourage spontaneous reduction. Attempts at manually reducing an incarcerated inguinal hernia should be performed by an experienced surgeon. If necessary, sedation to calm the infant before attempting manual reduction may be cautiously used. Ice packs should be avoided in infants and children. Following successful reduction of an incarcerated

hernia, expedient elective repair of the hernia should be performed after the edema has subsided. If reduction of an incarcerated hernia requires several attempts and is difficult, overnight inpatient observation is warranted to rule out reduction of strangulated bowel; fortunately, this is an uncommon occurrence in the pediatric population. Inability to reduce an incarcerated hernia is a clear indication for urgent operative exploration and repair. Incarcerated inguinal hernia must be differentiated from an acute, noncommunicating hydrocele or inguinal lymphadenitis. With acute hydrocele, it is usually possible to transilluminate the hydrocele and palpate normal cord structures above the scrotal mass. Additionally, symptoms of bowel obstruction are absent with acute hydrocele. Acute lymphadenitis typically is associated with fever, erythema, and tenderness, and there may be a history of lower-extremity infection on the ipsilateral side. If the inguinal mass is not reducible and an incarcerated hernia cannot be excluded, urgent groin exploration is required.

Operative Considerations and Outcome. The diagnosis of inguinal hernia in an infant or child is an indication for operative repair. The rationale for elective repair is to prevent the complications associated with incarceration. At least 71% of infants who require operative reduction of incarcerated inguinal hernia are younger than 11 months.²⁸ Therefore, an approach emphasizing timely elective repair of inguinal hernia is warranted, particularly during infancy. Delay of elective repair may be necessary in premature, extremely low birthweight (<1,500 g) infants and in

children with other conditions such as congenital heart disease, pulmonary disease, infection, or metabolic disease.

Elective inguinal hernia repair in the pediatric age group is usually performed as an outpatient surgical procedure using general anesthesia, although spinal anesthesia is an effective alternative in selected high-risk infants.²⁹ A regional caudal block or local inguinal nerve block using local anesthetic is useful to diminish perioperative pain and increase patient comfort. These techniques, along with the use of rapid-acting general anesthetics, allow the vast majority of children to be discharged home within hours of operation. Overnight observation and monitoring are required for high-risk infants and children with disorders that increase anesthetic risk for postoperative apnea.

Repair of pediatric inguinal hernia relies on high ligation of the hernia sac at the internal inguinal ring. Sensory nerves deep to the external oblique aponeurosis should be identified and preserved. Careful identification and dissection of the hernia sac from the vas deferens and the testicular blood supply must be performed. The vas deferens must be carefully dissected free from the sac, and direct handling or pinching of the vas with forceps is avoided. The absence of a vas deferens or a blind-ending vas may be observed in children with cystic fibrosis (CF). In female infants, opening the hernia sac to visualize the ovary and fallopian tube may help to avoid inadvertent injury to these structures during suture ligation of the sac. The distal component of the hernia sac is opened widely, and any fluid in the sac is evacuated. If the internal inguinal ring is attenuated or enlarged, it can be repaired with a few sutures. Experience with laparoscopic inguinal hernia repair using purse-string suture closure of the patent internal ring without direct inguinal exploration has been described.³⁰ The testicle is returned to its scrotal position by gentle traction on the gubernaculum, and the spermatic cord is carefully aligned along the inguinal canal. Postoperative pain is managed with oral acetaminophen for 24 to 48 hours; older children may require postoperative narcotics.

Operative exploration of the asymptomatic contralateral groin remains controversial but is often performed in infants younger than 2 years because of the reported 60% to 70% incidence of a patent processus vaginalis on the opposite side.³¹ In a survey of the surgical section of the American Academy of Pediatrics, 65% of the respondents perform contralateral exploration in male patients younger than 2 years, and 84% perform exploration for female infants up to age 4 years.³² Direct visualization of the contralateral groin can be performed using a laparoscope inserted either through the umbilicus or through a side-viewing laparoscope inserted through the hernia sac. Experience with diagnostic laparoscopy demonstrates that approximately one third to one half of children have a patent processus vaginalis on the contralateral, asymptomatic groin, with higher rates in infants younger than 1 year.^{33,34} This approach avoids unnecessary contralateral groin exploration in about half of all children who undergo surgery for unilateral inguinal hernia. However, the presence of a patent processus alone does not necessarily translate into a clinically significant hernia, and via systematic review, the reported risk of developing a metachronous contralateral inguinal hernia following open unilateral hernia repair in children is 7.2%.³⁵

The major risk of inguinal hernia repair in infants and children is related to general anesthesia. Complications in pediatric inguinal hernia repair include wound infection, injury to the vas deferens or testicular vessels, injury or displacement of the testicle, and recurrence. Fortunately, all these complications are infrequent. The overall complication rate is higher for children requiring emergent operation for incarcerated or strangulated hernia. Recurrent inguinal hernia following elective repair is unusual and may be an indication of an underlying connective tissue disorder such as Ehlers-Danlos syndrome.

Hydrocele

A *hydrocele* is a fluid collection that resides in the tunica vaginalis in the scrotum or the processus vaginalis in the inguinal canal. A hydrocele may be present at birth, or it may occur acutely as a result of an incarcerated hernia or torsion of the appendix testis. On examination, a hydrocele transilluminates with a bright handheld light. A hydrocele is described as either *communicating* or *noncommunicating* depending on whether there is direct patency between the hydrocele and the peritoneal cavity. A history of intermittent fluctuation in the size of the hydrocele is generally diagnostic for communicating hydrocele. A communicating hydrocele is synonymous with a patent processus vaginalis, and therefore, a communicating hydrocele is treated operatively in the same fashion. In male patients, a hydrocele of the cord is a collection of fluid in the processus vaginalis separate from the tunica vaginalis. In female patients, fluid trapped in the processus vaginalis is considered a hydrocele of the canal of Nuck. In noncommunicating hydrocele, the isolated fluid collection is typically asymptomatic and tends to spontaneously resolve before age 12 months. Operative management of noncommunicating hydrocele is usually reserved for lesions that persist after this age, acute enlargement of the hydrocele, or if there is any question of communication.

GASTROINTESTINAL DISORDERS

Neonatal Intestinal Obstruction

Various congenital anatomic defects, inherited metabolic diseases, and acquired physiologic disorders may present as intestinal obstruction in a newborn. Neonatal intestinal obstruction is characterized clinically by bilious emesis and is often associated with abdominal distention. Bilious emesis in a neonate must be considered to be acute mechanical intestinal obstruction until proven otherwise. Emergent surgical evaluation is warranted for any newborn with bilious emesis. Table 107.2 provides differential diagnoses for neonatal intestinal obstruction along with salient features of the history, physical examination, and diagnostic studies.

The clinical presentation of neonatal intestinal obstruction depends, in part, on the site of obstruction and the age of the infant. Clinical examination of the infant typically provides the surgeon with a preliminary diagnosis and helps guide further diagnostic studies. Abdominal distention is a characteristic physical finding with distal bowel obstruction, whereas the abdomen may be flat in proximal obstruction. The presence of bile in the gastric contents or stool provides clinical evidence of the location of an obstruction relative to the ampulla of Vater. Bilious emesis in an infant or child should be considered an anatomic obstruction requiring emergent surgical evaluation. An infant with bilious emesis who has already passed meconium and has tolerated feeding is unlikely to have intestinal atresia and more likely to have intestinal malrotation with midgut volvulus. If volvulus is suspected, emergent evaluation must be performed to diagnose and prevent catastrophic bowel injury or death.

Definitive diagnosis of neonatal intestinal obstruction may often be made by physical examination and readily available radiologic studies. Incarcerated inguinal hernia is an important cause of neonatal bowel obstruction, and examination leads to a straightforward diagnosis. Some congenital conditions have clearly recognizable features and may be associated with anatomic intestinal obstruction. For example, infants with trisomy 21 have a higher probability of having duodenal atresia or Hirschsprung disease than the general population. An approach to imaging the neonate suspected of having an intestinal obstruction is to obtain a plain abdominal radiograph, followed by either a contrast enema or an upper gastrointestinal series. Plain films of the newborn abdomen can be

TABLE 107.2

DIAGNOSIS

NEONATAL INTESTINAL OBSTRUCTION

■ DIAGNOSIS	■ HISTORY	■ PHYSICAL EXAMINATION	■ DIAGNOSTIC STUDIES
Intestinal atresia or stenosis	Bilious emesis	Abdominal distention	Plain abdominal film
	Failure to pass meconium	Abdominal distention	Contrast enema
Duodenal atresia or stenosis	Bilious or nonbilious emesis	Gastric distention	Plain abdominal film
	Feeding intolerance	Trisomy 21	Upper GI contrast study
Imperforate anus	Failure to pass meconium	Absent anus or visible fistula	Plain chest, abdominal film
	Bilious emesis (late)	Abdominal distention	Ultrasound kidneys, sacrum, rectum
		VACTERL association	Echocardiogram
Necrotizing enterocolitis	High-risk, premature infant	Abdominal distention	Plain abdominal film
	Bilious emesis	Abdominal wall erythema Hematochezia, guaiac-positive stool	
Meconium ileus	Cystic fibrosis (10%)	Acholic meconium	Plain abdominal film
	Bilious emesis	Abdominal distention	Contrast enema
Malrotation	Bilious emesis	No abdominal distention	Plain abdominal film
	Term, healthy infant		Upper GI contrast study
Hirschsprung disease	Delayed passage of meconium	Abdominal distention	Plain abdominal film
	Bilious emesis	Trisomy 21	Contrast enema
Uncommon causes of obstruction (intussusception, Meckel diverticulum, duplication)		Abdominal mass, incarcerated hernia	Variable
Medical conditions associated with ileus	Bilious emesis	Sepsis, hypothyroidism, etc.	Plain abdominal film

GI, gastrointestinal; VACTERL, vertebral, anal, cardiac, tracheal, esophageal, renal, and limb anomalies.

extremely useful because swallowed gas acts as a contrast agent. For example, duodenal atresia gives rise to a dilated, gas-filled stomach and duodenum proximal to the obstruction; the remainder of the bowel remains gasless, giving rise to the “double-bubble” appearance on plain films. Other causes of proximal intestinal obstruction may lead to a microcolon on contrast enema, which is a small, unused but otherwise normal colon. If a retrograde contrast enema does not pass into the dilated segment of bowel, an upper gastrointestinal series may be useful to identify a more proximal obstruction. Upper gastrointestinal series is also the most useful diagnostic test for intestinal malrotation.

Several medical conditions of the newborn appear clinically similar to mechanical intestinal obstruction (Table 107.2). In particular, bilious emesis from ileus secondary to neonatal sepsis is not uncommon. Congenital hypothyroidism is an infrequent and medically treatable condition that can produce delayed intestinal motility that mimics mechanical intestinal obstruction.

Intestinal Atresia or Stenosis

Embryology and Anatomy. The embryonic intestine undergoes segmental development during the third week of gestation. The septum transversum demarcates the developing foregut from the midgut. The midgut can be considered a tubular structure that progressively undergoes several predictable, developmental stages: (a) elongation; (b) herniation from and reduction into the coelomic cavity; (c) rotation; and (d) fixation of the mesentery to the posterior body wall.

Several different types of intestinal atresia are clinically observed (Fig. 107.7). *Type I* atresia is an intraluminal web or diaphragm that can either be complete or fenestrated with intact seromuscular layers of bowel. *Types II* and *IIIa* atresia are believed to be a result of in utero mesenteric vascular accidents. Experimental interruption of the fetal mesenteric blood supply in utero leads to this type of atresia.^{36,37} *Type IIIb* atresia, also known as the *apple-peel* or *Christmas tree deformity*, has complete mesenteric discontinuity, with the distal bowel concentrically surrounding a singular mesenteric blood supply. *Type IV* atresia has multiple segmental areas of discontinuous bowel. *Types IIIb* and *IV* atresia are thought to be consequences of major and multiple fetal mesenteric vascular interruption.

At least 90% of infants with congenital intestinal obstruction of the small bowel have complete atresia, whereas the remaining children have either stenoses or fenestrated intraluminal webs. The most common location is the distal ileum, and multiple areas of atresia are discovered in 3.6% to 20% of these infants.³⁸ Infants with fenestrated intraluminal webs may have a small, often eccentric opening only millimeters in diameter. These infants may not have obstructive symptoms until the introduction of solid food at 6 to 12 months of age and present with feeding intolerance, failure to thrive, or abdominal pain.

Congenital colonic atresia is a distinctly unusual condition. In a contemporary series of 277 infants treated with intestinal atresia, only 21 children had colonic atresia.³⁸ Similar to small bowel atresia, colonic atresia is believed to reflect fetal mesenteric vascular injury. Given the distal nature of colonic atresia, initial feeding may be well tolerated and definitive diagnosis may be delayed for several days. The diagnostic evaluation

FIGURE 107.7. Classification of intestinal atresia. Type I, muscular continuity with a complete web. Type II, mesentery intact, fibrous cord. Type IIIa, muscular and mesenteric discontinuous. Type IIIb, apple-peel deformity. Type IV, multiple atresias. (Adapted from Grosfeld JL. Jejunoileal atresia and stenosis. In: O'Neill JA Jr, Rowe MI, Grosfeld JL, et al. eds. *Pediatric Surgery*, 5th ed. St. Louis, MO: Mosby; 1998:1145–1158.)

and surgical treatment of colonic atresia is identical to the approach used for small bowel atresia. Colonic atresia may be associated with abdominal wall defects, skeletal or cardiac defects, or coexisting small intestinal atresia.

Clinical Presentation. The actual incidence rate of congenital intestinal atresia is unknown. Reported estimates in the United States are 3.5 to 3.75 cases per 10,000 total births.³⁹ Infants with jejunal or ileal atresia have a low incidence rate of significant associated anomalies. Approximately 10% of infants with gastroschisis have intestinal atresia or stenosis secondary to mechanical interruption of the mesenteric vascular supply.

Detection of maternal polyhydramnios on routine prenatal ultrasound screening can be an indication of proximal bowel obstruction caused by the interruption of normal amniotic fluid absorption in the fetal gut.⁴⁰ Following delivery, the classic clinical presentation of intestinal atresia is bilious emesis, abdominal distention, and failure to pass meconium. The degree of abdominal distention depends on the site of obstruction, the infant's age, and the efficacy of proximal decompression. Abdominal distention may be absent with proximal intestinal atresia. Distal intestinal atresia may lead to abdominal distention with visible or palpable intestinal loops on examination. Rectal examination and evaluation of stool character remains important when intestinal obstruction is suspected.

Diagnosis. Following history and physical examination, plain radiographic abdominal films should be obtained. Plain films in jejunal or ileal atresia demonstrate marked gaseous distention of the proximal intestine with gasless distal small bowel and colon. Haustral markings are normally not apparent in the neonatal colon, and therefore discrimination between small bowel and colon in the newborn is difficult without intraluminal contrast. A contrast enema is generally obtained to confirm the diagnosis of jejunoileal atresia. A diminutive, unused but otherwise normal microcolon is typical of proximal intestinal obstruction. The inability to reflux contrast into the proximal, dilated small bowel segment is diagnostic for congenital intestinal obstruction. This radiographic finding, in conjunction with the clinical setting, warrants operative exploration. An upper gastrointestinal series is unnecessary and may increase the risk of further emesis and aspiration in the newborn with obstruction. Incomplete obstruction from a fenestrated intraluminal web may require more sophisticated imaging techniques such as catheter-directed enteroclysis.

Treatment. Anatomic lesions causing neonatal intestinal obstruction require operative treatment. Whereas malrotation with midgut volvulus requires emergent diagnostic workup and operative intervention, obstruction resulting from intestinal atresia is generally not associated with life-threatening physiologic disturbances. Therefore, initial treatment is aimed at treating any other associated problems, confirming diagnosis, and preparing the infant for an operation. During this period, the infant always should have an orogastric or nasogastric tube in place to provide proximal decompression of the obstructed bowel.

The operative strategy in treating intestinal atresia is to restore gastrointestinal tract continuity while preserving as much intestinal length as possible. The operation is straightforward, and an end-to-end or end-to-oblique (end-to-back) anastomosis is typically performed (Fig. 107.8). Short segmental bowel resection and excision of an intraluminal web or diaphragm are used when necessary. Visual inspection and instillation of intraluminal saline or air to exclude distal atresia or web prior to anastomosis is important to evaluate patency of the downstream bowel. The size discrepancy between the proximal and distal bowel is usually considerable, and delayed postoperative bowel motility is common. Some surgeons advocate the use of technical procedures to improve emptying of the proximal bowel by reducing overall bowel diameter. These procedures include resection, plication, and tapering enteroplasty.

FIGURE 107.8. A and B: The end-to-oblique anastomosis for small bowel atresia. C: An extension of the distal enterostomy along the antimesenteric border may be used to create proximal and distal lumens of equal size for anastomosis.

Complex atresia associated with apple-peel deformity or multiple segmental atresias may require multiple serial anastomoses to preserve as much bowel length as possible. The ileocecal valve is preserved whenever possible, allowing improved tolerance of enteral nutrition in infants with limited small bowel length. It is estimated that approximately 40 cm of small bowel without an ileocecal valve, compared with 15 to 20 cm with an ileocecal valve, is sufficient for long-term enteral feeding tolerance in the neonate.⁴¹ Contemporary management of colonic atresia includes primary anastomosis when technically possible.

Results and Outcome. Currently, the overall survival rate for infants treated for intestinal atresia or stenosis (including duodenal atresia) exceeds 93% in most large series.^{38,42} Mortality in these infants is generally related to cardiac anomalies, birthweight less than 2 kg, and associated congenital anomalies.⁴³ Infants with a limited amount of intestinal length for nutritional absorption (short bowel syndrome with less than 40 cm) usually require long-term TPN and are at moderate to high risk for sepsis and liver injury. Infants with normal gastrointestinal length may still have prolonged intestinal dysfunction and dysmotility for several weeks.

Congenital Duodenal Obstruction

Causes of duodenal obstruction in the newborn include duodenal atresia or stenosis, duodenal intraluminal web, and

annular pancreas. Because of the common embryologic basis, clinical presentation and treatment, these entities are considered jointly.

Embryology and Anatomy. The duodenum is derived from both the caudal segment of the foregut and the cranial segment of the midgut. Duodenal development is intimately related to the developing pancreaticobiliary system. The fetal pancreas arises from paired dorsal and ventral foregut diverticula during week 6 of gestation. The dorsal anlage gives rise to the body and tail of the pancreas as well as the main pancreatic duct. The ventral anlage migrates 180 degrees to fuse with the dorsal gland, forming the uncinus process and the distal portion of the duct of Wirsung (Fig. 107.9). An annular pancreas is characterized by glandular persistence surrounding the duodenum at the site of the embryonic ventral anlage. It is invariably associated with intrinsic duodenal obstruction, and a patent accessory pancreatic duct is common (Fig. 107.10).⁴⁴

It is believed that congenital duodenal obstruction results from abnormalities of pancreatic development, failure of duodenal recanalization, or vascular compromise to the duodenum. Duodenal atresia may occur with or without seromuscular continuity, and an intraluminal duodenal web may occur with or without fenestration. The most frequent location for duodenal atresia is in the descending duodenum distal to the ampulla of Vater. Most series report a 5% to 10% incidence of duodenal atresia proximal to the ampulla, giving rise to nonbilious gastric contents and emesis. Another important variant is a periampullary web projecting distally into the duodenal or jejunal lumen, forming a “wind sock” deformity (Fig. 107.11). In this instance, the ampulla must be clearly identified before excision and repair because of the proximity of the ampulla to the web.

Clinical Presentation. The incidence rate of congenital duodenal obstruction is estimated to be about 1 in 6,000 to 10,000 births.⁴⁵ About 30% of these infants have trisomy 21.⁴⁶ Infants born with duodenal atresia should be examined with a high degree of suspicion for trisomy 21 and undergo routine karyotype analysis. Other associated anomalies such as congenital heart disease, genitourinary tract malformations, and musculoskeletal disorders are common in these infants, and appropriate preoperative workup is necessary.

Congenital duodenal obstruction most commonly presents in the first 24 to 48 hours of life with feeding intolerance and bilious emesis; duodenal obstruction proximal to the ampulla of Vater results in nonbilious emesis. On physical examination, infants with untreated duodenal obstruction may have a palpable epigastric mass, and gastric peristaltic waves may be visible. The collapsed and unused distal small intestine typically does not produce diffuse abdominal distention. Partial duodenal obstruction from a fenestrated web may not produce symptoms in the newborn period, and delayed diagnosis is common.

Diagnosis. Prenatal diagnosis of duodenal atresia is possible given contemporary fetal ultrasound techniques. Following birth, infants with suspected duodenal atresia should undergo plain abdominal radiographs. The classic radiographic finding of duodenal atresia is a double bubble from the air-filled stomach and duodenum (Fig. 107.12). In complete duodenal obstruction, no gas is seen distal to the duodenum; in this setting, the plain film is sufficiently diagnostic that no further imaging of the gastrointestinal tract is necessary. If there is incomplete obstruction, gas may be seen distally in the small or large intestine. Infants with suspected incomplete obstruction at the duodenal level may have either a fenestrated web or volvulus secondary to malrotation. Given the need for emergent operative intervention in malrotation with acute volvulus, an urgent upper gastrointestinal series with contrast should be strongly considered to exclude a neonatal surgical emergency. It is important that all anatomic lesions causing neonatal duodenal obstruction require operative repair using a similar approach.

FIGURE 107.9. Normal embryologic development of the duodenum, pancreas, and bile ducts. **A:** Fifth gestational week. **B:** Sixth week. **C:** Seventh week. **D:** Eighth week.

Treatment. Following expedient treatment of any associated life-threatening medical conditions and preoperative evaluation, the operative goals are to restore gastrointestinal continuity without sacrificing intestinal length or absorptive surface area. Because most lesions causing congenital duodenal obstruction are near the ampulla of Vater, great care must be exercised in treatment to avoid inadvertent injury to the ampulla or pancreas.

Congenital duodenal atresia is treated by duodenoduodenostomy. Duodenal obstruction secondary to annular pan-

creas is also treated by duodenoduodenostomy. Direct division of annular pancreas is not performed because this does not address the underlying intraluminal duodenal obstruction, and there is significant risk of injury to the accessory pancreatic duct (Fig. 107.10).

Duodenoduodenostomy is performed by making a transverse incision in the dilated, proximal duodenum and a longitudinal incision in the unused, downstream duodenum. The lumens are sutured together to form a diamond-shaped anastomosis (Fig. 107.13).⁴⁷ Downstream duodenal patency should

FIGURE 107.10. Annular pancreas. **A:** The associated duodenal atresia is shown. **B:** The relationships of the annular pancreas to the common bile duct and main and accessory pancreatic ducts are shown in cross section.

FIGURE 107.11. Anatomic forms of duodenal atresia (A–C) and webs (D and E). In particular, E demonstrates the unique wind-sock deformity. This lesion is important and potentially confusing because the point of obstruction is not at the apparent point of change in luminal diameter.

FIGURE 107.12. Classic radiographic appearance of duodenal atresia. There is a double bubble of gas in the stomach and proximal duodenum, with no gas in the distal intestinal tract.

be demonstrated by passing a catheter or infusing saline or air distally to avoid overlooking synchronous distal intestinal atresia. Successful and efficacious laparoscopic duodenal atresia repair has also been reported.⁴⁸

Duodenal webs are excised through a longitudinal duodenotomy. The wind sock duodenal web must be clearly identified because the visible transition from the distended, proximal duodenum to the small, downstream duodenum may be several centimeters distal to the base of the web. The ampulla of Vater must be unequivocally identified before duodenal web excision to avoid injury. Closure of the longitudinal duodenotomy is performed transversely to avoid narrowing of the duodenum.

There is usually great size discrepancy between the dilated, proximal pouch and the distal duodenal lumen, leading some surgeons to advocate procedures designed to reduce the diameter of the proximal duodenum in an effort to facilitate improved postoperative bowel motility. The efficacy of these procedures, which include tapering duodenoplasty and duodenal plication, has been described in anecdotal fashion without randomized comparison.

Results and Outcome. After successful operative repair of duodenal atresia or stenosis, delayed gastric emptying is common and typically manifests as enteral feeding intolerance.

FIGURE 107.13. Diamond-shaped duodenoduodenostomy for repair of duodenal atresia.

Patience and persistence are essential during the postoperative period. Surgical outcomes after repair of congenital duodenal obstruction are excellent,^{46–49} with perioperative survival exceeding 95%. Perioperative mortality is generally related to other congenital anomalies, and in particular, congenital heart disease in infants with trisomy 21. Other late problems may be encountered that reflect gastroduodenal motility issues such as poor gastric emptying, gastroesophageal reflux, and duodenal

dilatation. These symptoms may appear several months to years following repair, and therefore, long-term surgical follow-up remains important.

Anorectal Malformations (Imperforate Anus)

Embryology. By week 5 of gestation, the fetal cloaca is identifiable with the adjacent hindgut, allantois, and vestigial tailgut (Fig. 107.14). The mesoderm of the urorectal septum extends caudally to fuse with the cloacal closing plate. Fusion of the lateral cloacal ridges completes division of the cloaca into the rectum and the urogenital sinus. The caudal aspect of the urorectal septum forms the perineal body. The anal membrane normally ruptures during week 8 of gestation, completing the patency of the distal rectum to the skin. Further development of the urogenital sinus leads to the formation of the urethra and bladder. In female infants, the uterus and proximal vagina develop from the müllerian ducts. The diverse anatomic variation observed with anorectal malformations is thought to reflect anomalous or interrupted development of these structures during normal embryogenesis.

Anatomy and Classification. The normal anatomy of the anus and rectum is reviewed in previous chapters. Normally, the rectum descends to the perineum and ultimately, to the anal orifice through a striated muscle complex in the pelvis resembling a funnel. The striated muscle complex is under voluntary control and is responsible for providing fecal continence (Fig. 107.15). Contiguous portions of the *levator ani*, the *external sphincter*, and the *puborectalis* muscles compose the *striated muscle complex*. These anatomically indistinct components of the muscle complex act together to provide control of defecation. The concept of the striated muscle complex and anatomic relationships leading to normal fecal continence with respect to anorectal malformations has evolved from both clinical and anatomic data as described by Peña.⁵⁰

Because of the variety of anorectal malformations observed, different classification systems have been proposed in an attempt to characterize the defects. A summary of the Wing-spread classification is provided in Table 107.3. This anatomically descriptive classification scheme is useful in planning the operative management of anorectal malformations.

In male subjects, the two most common anorectal malformations observed are low imperforate anus with a perineal fistula (Fig. 107.16) and high anorectal agenesis with a rectoprostatic

FIGURE 107.14. Normal embryologic division of the cloaca by the urorectal septum into the ventral urinary tract and the dorsal rectum. This process is normally completed by the ninth or tenth week of gestation.

FIGURE 107.15. The normal relations of the pelvic striated muscle complex and the rectum. **A:** Normal male anatomy. **B:** Coronal view showing individual components of the striated muscle complex. **C:** Sagittal view of normal anatomy.

urethral fistula (Fig. 107.17). Male patients without a visible perineal fistula are assumed to have high imperforate anus with a rectourethral fistula until proven otherwise. In female subjects, the most common malformation encountered is low imperforate anus with a fistula from the rectum to either the perineal body or the vaginal vestibule (Fig. 107.18). As these malformations result from developmental arrest at various times during migration of the urogenital septum, considerable anatomic variability exists in both male and female subjects.

A common anatomic feature of imperforate anus is incomplete rectal descent to the perineum. Consequently, the rectum is not completely within the striated muscle complex. The caudal portion of the striated muscle complex remains a solid mass of striated muscle, whereas the cephalad portion may be normally positioned circumferentially around the rectal pouch. In low imperforate anus, the rectum nearly reaches the perineum and the configuration of the striated muscle complex

surrounding the rectum more closely approximates normal. With high imperforate anus, less striated muscle surrounds the rectal pouch. All anorectal malformations are considered to have some component of striated muscle complex hypoplasia and dysfunction, although the physiologic effects are variable. Low anorectal lesions have a more favorable prognosis for fecal continence than intermediate or high lesions.

Classic delineation between low and high anorectal malformations is made anatomically at the pubococcygeal line. The vast majority of low lesions have associated perineal or vestibular fistulas. High imperforate anus has a blind-ending rectal pouch above the pubococcygeal line and, therefore, above the striated muscle complex (or levator ani).

Associated Anomalies. Associated anomalies in infants with anorectal malformations are common and may be found in more than 70% of patients. The VACTERL (vertebral, anal,

cardiac, tracheal, esophageal, renal and limb) association is important and requires consideration in any infant with imperforate anus. *Vertebral anomalies* are common and include sacral dysplasia and agenesis. Infants with sacral anomalies commonly have high imperforate anus and sacral nerve dysfunction that can lead to poor long-term fecal continence and neurogenic bladder. Various spinal cord malformations also can be

FIGURE 107.16. Male infant with low imperforate anus and perineal fistula. Note that the fistula is anterior to the striated muscle complex.

observed in these infants, including tethered spinal cord syndromes and some myelodysplastic syndromes. During the neonatal period, these spinal lesions may be detected by using ultrasound or magnetic resonance imaging (MRI), and surgical treatment may be necessary within the first 8 to 18 months of life. *Tracheoesophageal* fistula with or without esophageal atresia is estimated to occur in about 10% of infants with anorectal malformations. *Renal anomalies* are the most common associated abnormalities with anorectal malformations and include both upper and lower tract conditions. Genitourinary screening in the form of a renal ultrasound and voiding cystourethrogram is routinely performed. *Cardiac* anomalies are common, and screening echocardiography is clinically indicated. *Limb abnormalities*, in particular, involvement of the radius, complete the associated anomalies defined by the acronym.

Clinical Presentation. The incidence rate of anorectal malformations is estimated at 1 in 2,524 to 5,000 live births,⁵¹ with a slightly higher rate in males. Careful examination of the neonatal perineum reveals the diagnosis. If unrecognized and left untreated, high imperforate anus eventually leads to signs and symptoms of complete bowel obstruction characterized by abdominal distention, feeding intolerance, and bilious emesis. Because of the nearly uniform rectourethral or rectovesicular fistula in males with high lesions, some of these infants will pass meconium or gas through the urethra during urination. In contrast, infants with low malformations typically pass meconium through a perineal or vestibular fistula within the first 24 hours of life. Occasionally, infants with large perineal fistulas are not diagnosed with an anorectal malformation until progressive constipation is noted weeks to months after birth.

In male infants, more than 95% of low malformations are associated with either a thin anal membrane or a fistula to the perineum or scrotal raphe. The presence of a “bucket handle” skin deformity at the presumptive anal dimple is also diagnostic of a low lesion. Infants with high malformations typically lack anal skin dimpling, have a flat gluteal contour, and may have little or absent contraction of the external sphincter with cutaneous stimulation. In female infants, 90% to 95% of low malformations have a perineal or vestibular fistula. In both male and female infants, a perineal fistula may not become apparent in the first 12 to 24 hours of life until meconium progresses distally through the rectum into the fistula.

Diagnosis. Because surgical treatment of a high or intermediate anorectal malformation is different from that for low lesion, a primary diagnostic goal is to determine whether an infant with imperforate anus has a high or low malformation. A secondary diagnostic goal is to determine the specific anorectal malformation as it relates to the rectourethral or rectovesicular fistula.

Clinical examination of an infant with low imperforate anus almost always reveals an external fistula to the perineum or vestibule. The classic radiographic study of newborns with imperforate anus is the Wangenstein-Rice invertogram, with a lateral view of the pelvis obtained 12 to 24 hours after birth with the infant in a head-down position. This technique has been largely replaced by ultrasound-directed imaging.⁵² Real-time ultrasound is currently well accepted as an accurate method of determining the distal extent of the rectal pouch. Computed tomography (CT) imaging and MRI can be useful in evaluating the pelvic striated muscle complex in difficult cases, and in particular, cloacal malformations. MRI is also useful in evaluation of the distal spinal cord in these infants.

If there is a suspected perineal fistula or covered anus, diagnostic needle aspiration under anesthesia may be useful. Aspiration of meconium not only localizes the rectum or fistula, but it also can provide an estimation of the distance between the perineum and the rectum or the fistula. In general, low lesions are within 1 cm of the perineum. An infant not clearly found to have a low lesion by physical examination, radiographic studies, or examination under anesthesia should

FIGURE 107.17. Male infant with high imperforate anus, showing the pubococcygeal line, ischium, and striated muscle complex. **A:** The rectal pouch ends cephalad to the pubococcygeal line. This location of the rectourethral fistula is typical. **B:** Coronal view showing incomplete development of the rectal pouch within the striated muscle complex. The rectourethral fistula is shown.

FIGURE 107.18. Female infant with low imperforate anus and vestibular fistula.

be considered to have a high anorectal malformation and treated accordingly.

A voiding cystourethrogram is generally the procedure of choice for defining the rectourethral or rectovesical fistula. In some instances, cystoscopy is a useful adjunct before repair of high imperforate anus. For example, an infant with a large rectourethral fistula may require cystoscopic guidance of a urinary catheter to avoid inadvertent placement of the catheter through the fistula and into the rectum.

Treatment. Imperforate anus by itself is not a life-threatening condition, and, in many instances, observation for 12 to 24 hours may help to delineate the presence or absence of a fistula. The surgical management of anorectal malformations has been well described elsewhere,⁵⁰ and a brief summary follows below.

Low Malformations. Definitive repair of most low anorectal malformations can be performed in the newborn period with perineal procedures that do not require diverting colostomy. Simple dilatation of the fistula or unroofing of a covered anus may relieve the anatomic obstruction. For more complex anal stenoses or anterior perineal fistulas, a formal perineal anoplasty may be required. A common perineal procedure performed is cutback anoplasty, in which the anterior fistula or anal orifice is opened posteriorly by dividing the perineum to the external sphincter. More complex alternative approaches may be preferred in female infants with low vaginal or anterior

perineal fistulas. These lesions generally require circumferential mobilization of the anterior fistula with transposition to the center of the external sphincter. Anterior reconstruction of the perineal body is then performed. Transposition anoplasty is designed to position the neoanus within the center of the external sphincter and separate the neoanus from the vaginal introitus.

Intermediate and High Malformations. Infants determined to have an intermediate, high, or indeterminate anorectal malformation generally require diverting divided colostomy as initial surgical management. Care must be taken to ensure that the proximal diverting colostomy provides adequate length and mobility of the distal colon in anticipation of eventual anorectoplasty. A divided colostomy is preferred over a loop colostomy by many surgeons to provide maximal fecal diversion from the downstream rectourinary fistula. Following diverting colostomy, a distal contrast study into the rectal pouch can also define the fistula and delineate the position of the rectum relative to the perineum.

Anorectoplasty is generally performed when the infant is approximately 8 to 12 months of age. Many different approaches have been described, and considerable personal and institutional variation is common. No single approach has superior results, and all have technical merits and difficulties. The common surgical objectives in the treatment of anorectal malformations include the following: (a) relieve the rectal obstruction; (b) create a new anus; (c) position the rectum as normally as possible within the striated muscle complex; and (d) divide the rectourinary fistula. In addition, preservation of the surrounding structures (prostate, urethra, seminal vesicles, vaginal wall) is essential.

For repair of high and intermediate anorectal malformations, the most widely used procedure in the United States is the posterior sagittal anorectoplasty described in detail by Peña.⁵⁰ The infant is placed prone, and a posterior sagittal incision following the gluteal crease is used. The external sphincter and the striated muscle complex are divided posteriorly along the midline to expose the rectal pouch. A muscle stimulator is used to define and map the striated muscle complex and to confirm symmetric dissection along the midline. Typically, the rectal pouch can be adequately dissected by this approach to allow enough length to reach the perineum. Infrequently, a combined abdominoperineal approach is required. The mobilized rectal pouch is opened and the rectourinary fistula identified and closed directly. The rectal pouch is placed centrally within the striated muscle complex, which is reconstructed circumferentially around the rectum. The neoanus is centered within the external sphincter, and the mucosa is sutured to the perineum.

Other accepted and practiced surgical approaches to imperforate anus include a sacroperineal approach as proposed by Stephens,⁵³ and an approach that uses components of endorectal dissection as attributed to Rehbein.⁵⁴ Both these surgical procedures are characterized by blind pull-through of the distal rectum to the perineum without direct visualization of the striated muscle complex. Experience with laparoscopic dissection and division of the rectourinary fistula with perineal pull-through reconstruction has been reported.⁵⁵ It appears that personal preference, experience, and familiarity rather than differences in outcome dictate the selection of procedure. In general, diverting colostomy in all of these procedures is maintained until the anorectoplasty has completely healed, after which the colostomy is closed electively.

Results, Complications, and Outcome. Mortality following anorectoplasty is related to the presence of associated congenital anomalies other than imperforate anus. A careful review of 284 infants undergoing repair of anorectal malformations observed an 18.7% mortality,⁵⁶ suggesting that this group is at moderate to high risk for complications and death secondary to coexisting congenital anomalies.

Complications are similar to other gastrointestinal surgical procedures and include infection, leak, recurrent fistula, or anastomotic stricture. Leak or stricture formation is observed in 5% to 10% of infants undergoing tapering rectoplasty during posterior sagittal anorectoplasty. Anorectal strictures are treated by gradual postoperative anal dilatation for weeks to months. Recurrent rectourethral fistula or urethral stricture is uncommon.

Long-term functional outcome in infants with low malformations is generally good given the relatively normal descent of the distal rectum within the striated muscle complex. Infants with higher lesions have a less predictable prognosis and are much more likely to have difficulty with fecal continence. Currently, the outcomes appear to be independent of the type of surgical reconstruction performed and more related to anatomic patient factors, including degree of rectal descent, integrity of the striated muscle complex, and sacral innervation. Few or perhaps none of these children have completely normal bowel habits after operation. About half of the infants have acceptable to good results with episodic fecal soilage that can be improved with bowel management programs, enemas, and cathartics.⁵⁷⁻⁵⁹ A comprehensive bowel management program is essential in preventing fecal impaction and subsequent motility dysfunction in the rectum. The remaining children require major adjustments in lifestyle secondary to fecal incontinence, chronic constipation, or fecal smearing and odor. In some instances, socially acceptable continence can be assisted by the use of daily antegrade enemas via a cecostomy or appendicostomy. In other situations, a permanent diverting colostomy may be desirable.

Necrotizing Enterocolitis

4 Pathophysiology. NEC is a neonatal disease characterized by an initial intestinal mucosal injury that may ultimately progress to transmural bowel necrosis. NEC is the most frequently encountered neonatal surgical emergency and a major cause of morbidity and mortality in the premature infant. Despite its frequency and extensive study, the pathogenesis remains obscure, and surgical treatment is directed largely at controlling the complications of intestinal necrosis. The development of NEC occurs in association with various associated conditions, including perinatal stress, sepsis, respiratory failure, hypoxemia, hypotension, and congenital cardiac defects. In general, NEC is observed in the premature infant with multiple risk factors and potential etiologic events and conditions. Current clinical and experimental data support the concept that the pathophysiology of NEC remains enigmatic and multifactorial.

The intestinal mucosal injury observed in NEC is likely to be the end result of an ischemic insult in a susceptible host. Normally, the neonatal pulmonary and systemic vascular smooth muscle undergoes rapid structural and physiologic changes shortly after birth. The premature infant appears to be particularly vulnerable to vasoconstriction. With regard to NEC, it is hypothesized that hypoperfusion and ischemia of the premature neonatal intestinal tract may be the result of uncontrolled splanchnic vasoconstriction. This situation may be worsened in critically ill premature infants with low cardiac output states impairing oxygen delivery to the intestines.

A common characteristic of NEC is the host inflammatory response to the initiating mucosal injury. Experimental data are consistent with an important role for inflammatory mediators in the propagation of intestinal injury in NEC.⁶⁰ More than 90% of cases of NEC occur after the initiation of enteral feeding, and several studies document that the osmolality or rate of initial feeding may be important. Although controversy exists, most neonatal centers now avoid rapid advancement of hyperosmolar enteral feedings and attempt to prevent excessive fluid volume in premature infants.^{61,62} A multicenter, randomized controlled clinical trial using *Bifidobacterium* and

Lactobacillus as a probiotic given with initial feeding demonstrated significant reduction in death from NEC in very low birthweight premature infants.⁶³

The most common site of involvement of NEC is the terminal ileum and right colon. NEC may be localized, segmental, or it may involve the entire gastrointestinal tract. Histopathologic examination of intestinal tissue from infants with NEC demonstrates submucosal edema, hemorrhage, and microvascular thrombosis leading to transmural necrosis. The histopathology of NEC resembles that of experimental intestinal ischemia, with areas of reversible mucosal injury adjacent to areas of transmural necrosis. Dissection of intraluminal gas through the injured mucosa leads to gas within the bowel wall, known as *pneumatosis intestinalis*. The finding of pneumatosis intestinalis is a classic radiographic and pathologic feature of NEC. Initially, the gas may be localized in the submucosa or lymphatic vessels, but it may dissect into the muscularis, the portal venous tract, or into the subserosa. Intestinal perforation, inflammatory phlegmon, and diffuse peritonitis are common with advanced NEC.

Clinical Presentation. Over the past three decades, advancements in technology, prenatal care, and neonatology have improved overall outcome in premature infants who were previously unable to survive. In the United States alone, low birthweight infants (less than 2,500 g) account for more than 250,000 births a year. At least half of all infants with NEC are extremely low birthweight infants weighing less than 1,500 g. In a study of 302 infants with NEC treated over two decades, the average birth weight fell from 1,645 to 1,505 g, and in similar fashion, the mean gestational age fell from 32.4 weeks to 30.4 weeks.⁶⁴ NEC is estimated to occur in 1 to 3 of 1,000 live births and 30 per 1,000 low birthweight births.⁶⁵ NEC may also occur in term infants, and in this group, it has a tendency to involve the colon and may present without classic signs.⁶⁶ The actual incidence of NEC remains difficult to determine because the diagnosis is subjective; classic signs on physical examination and diagnostic imaging are not always uniformly present. The classic clinical signs of NEC include abdominal distention, feeding intolerance, bilious emesis, and either occult or gross blood in the stool. Gastrointestinal mucosal bleeding is present in the vast majority of cases (80%–90%) but is rarely significant from a hemodynamic standpoint. On physical examination, abdominal tenderness with distention is common, and individual loops of thickened or fixed bowel may be palpable. Edema, erythema, crepitus, or discoloration of the abdominal wall suggests intestinal necrosis, perforation, or intra-abdominal abscess (Fig. 107.19). Hematochezia or guaiac-positive stool is typical. Systemic signs of

FIGURE 107.19. Clinical presentation of diffuse staining of abdominal wall in an extremely low birthweight infant with perforated necrotizing enterocolitis.

inflammation and sepsis such as temperature instability, apnea, bradycardia, hypoxemia, acidosis, and thrombocytopenia are also common. The primary diagnostic goal during initial clinical evaluation is to determine whether irreversible, transmural intestinal necrosis is present. There is no single physical finding or laboratory test that makes this distinction.

Diagnosis. The diagnosis of NEC relies on clinical evaluation and judgment based on symptoms and signs in the appropriate setting. Table 107.4 summarizes diagnostic criteria and a staging system for NEC most commonly used in the United States.⁶⁷ Radiographic confirmation of NEC requires only plain abdominal films. During the acute inflammatory phase, contrast studies may be hazardous and are contraindicated. The classic radiographic finding of pneumatosis intestinalis (Fig. 107.20) confirms the diagnosis in the appropriate clinical setting but is variably present. Other radiographic findings consistent with NEC include thickened bowel loops, ascites, and portal venous gas. Serial abdominal films, including a left

Marked gastrointestinal hemorrhage

Abdominal radiographs showing pneumoperitoneum in addition to findings listed for stage II

Reproduced from Bell MJ, Kosloske AM, Benton C, et al. Neonatal necrotizing enterocolitis: prevention of perforation. *J Pediatr Surg* 1973; 8:601–605, with permission.

FIGURE 107.20. Plain abdominal film demonstrating pneumatosis intestinalis (arrows) in an infant with necrotizing enterocolitis.

lateral decubitus or upright film, should be obtained every 6 to 8 hours during the early course of the disease. These sequential studies help to document the progression or resolution of the inflammatory process and, importantly, evaluate for the presence of intestinal perforation presenting as free intraperitoneal gas or pneumoperitoneum. The presence of pneumoperitoneum mandates operative intervention; however, up to half of infants with perforated NEC do not have discernible pneumoperitoneum on plain films.

Treatment

Nonoperative. The vast majority of infants with NEC can be managed medically. Initial management of NEC includes proximal decompression with a nasogastric or orogastric tube, bowel rest, and broad-spectrum intravenous antibiotics. Prompt correction of hypotension, hypoxemia, and inadequate ventilation must be undertaken. Intravenous fluid management, with particular attention to electrolytes and acid-base status, is essential. Central venous access is secured and TPN is initiated. Oxygen delivery and cardiac performance must be maintained, which in a premature neonate may require operative closure of a patent ductus arteriosus; this approach is preferable over the use of indomethacin in the setting of NEC.⁶⁸ Serial physical examinations and blood work are useful in monitoring disease progress.

Most infants with NEC improve with medical management. Typically, reversal of the systemic inflammatory response occurs rapidly, and the abdominal distention and ileus resolve over a period of days. Nasogastric tube decompression and intravenous antibiotics are usually continued for 7 to 14 days. Enteral feeding usually is resumed once antibiotics have been discontinued and there has been return of gastrointestinal function. The usual course of medically treated NEC is rapid clinical response and stabilization in the first 24 to 36 hours. Infants with significant intestinal necrosis typically have signs of either pneumoperitoneum or clinical deterioration during the initial 24 to 72 hours of treatment.

Indications to abandon medical management and escalate surgical therapy include evidence of intestinal perforation or clinical deterioration with persistent or progressive systemic

illness despite maximal medical therapy. Evidence of persistent or progressive systemic sepsis includes temperature instability, refractory hypotension, acidosis, hypoglycemia, neutropenia, and thrombocytopenia. Local findings such as portal venous gas, abdominal wall cellulitis, or crepitus also may signal intestinal necrosis and the need for operative intervention. A palpable, fixed abdominal mass consistent with intestinal perforation with an inflammatory phlegmon or abscess also may be a relative indication for operation. Because there is not complete agreement on what constitutes clinical deterioration, some controversy exists regarding operative indications for NEC in the absence of pneumoperitoneum. Because the interpretation of clinical deterioration criteria remains subjective, the decision to operate remains a multifactorial clinical judgment. In equivocal situations, abdominal paracentesis of ascitic fluid may be helpful in diagnosing intestinal necrosis with perforation in the absence of pneumoperitoneum if the aspirate contains bacteria or stool.⁶⁹

Operative. Operative indications in NEC include the presence of intestinal necrosis with or without frank intestinal perforation. Conventional operative intervention is aimed at treating the complications of NEC (i.e., intestinal necrosis). In general, resection of intestine involved with NEC does not prevent further extension of disease in other involved areas of the bowel. For isolated segmental disease, the traditional surgical treatment of NEC is resection of necrotic bowel with proximal enterostomy and distal mucous fistula placement. In infants with diffuse NEC, multiple resections with several enterostomies may be required. The primary operative goal is an expedient operation with preservation of as much intestinal length as possible, including the ileocecal valve. Because the risk of developing short-gut syndrome is substantial in infants with diffuse disease, preservation of marginal areas of involved intestine with a planned second-look operation to reevaluate intestinal viability may be useful. Accurate measurement of the remaining bowel length is important from a diagnostic and prognostic standpoint, with the length of bowel resected determined by the extent of transmural intestinal necrosis. Resection with primary anastomosis in selected infants with NEC has been reported,⁷⁰ with a recent study observing recurrent NEC in 22% and strictures in 17% of 18 treated infants following primary anastomosis.⁷¹ Complete intestinal necrosis of the small intestine and colon is uncommon and is not compatible with long-term survival without the sequelae of short-gut syndrome and the potential need for intestinal transplantation (Fig. 107.21).

FIGURE 107.21. Fulminant necrotizing enterocolitis involving the entire gastrointestinal tract in a premature infant. Note the presence of pneumatosis intestinalis.

Infants with NEC are typically fragile and premature, and complications in this population are not well tolerated. Survival in this situation may be more dependent on disease severity and coexisting medical problems than the operative approach. For the high-risk, low birthweight infant, initial management with primary bedside peritoneal drainage rather than laparotomy and bowel resection may be useful as either a temporizing measure or, in some instances, a definitive procedure.⁷² A multicenter, randomized, controlled surgical trial comparing laparotomy with primary peritoneal drainage in premature infants with perforated NEC found that overall survival, dependence on TPN, and length of stay were independent of the type of operation performed.⁷³

Complications, Results, and Outcome. Most infants with NEC are treated successfully without operative intervention. Morbidity and mortality for this group are related primarily to problems associated with prematurity. Given the delay of bowel function and the need for TPN, cholestatic jaundice commonly occurs but is generally reversible. Infants placed on broad-spectrum antibiotics for an extended period are at risk for developing fungal sepsis. For infants with intestinal necrosis from NEC, infectious complications including wound sepsis, central venous catheter infections, and pneumonia with respiratory failure may occur.

The overall surgical complication rate in infants with NEC is at least 20% to 40%. Virtually every infant with NEC has a significant complication, an associated medical problem, or both. Immediate technical complications in treating NEC include intestinal leak, fistula formation, stoma necrosis, bleeding, and liver injury during exploration (Table 107.5). These complications are obviously magnified in the extremely low birthweight infant with preexisting intestinal injury. Fluid and electrolyte losses from proximal diverting enterostomies can be significant and even life threatening in extremely low birthweight infants whose circulating blood volume is less than 50 to 100 mL. A review of 68 infants treated surgically for NEC observed a 26% mortality rate and a 68% complication rate related to the stoma or its closure in the perioperative survivors.⁷⁴ Complications included intestinal stricture, incisional or parastomal hernia, stoma prolapse, intussusception, wound dehiscence or infection, small bowel obstruction, and anastomotic failure. The complications associated with diverting enterostomy in this unique population provide a compelling rationale for early enterostomy closure once the inflammation from peritonitis has resolved. A prospective, randomized trial comparing resection and enterostomy with resection and primary anastomosis in the treatment of NEC has not been reported.

TABLE 107.5 COMPLICATIONS

OPERATIONS FOR NECROTIZING ENTEROCOLITIS

Infection (wound, intra-abdominal, central venous catheter, pneumonia)
Bleeding
Stoma-related complications (stenosis, retraction, prolapse)
Electrolyte or nutritional disturbances from enterostomy output
Enterocutaneous fistula
Anastomotic leak, stenosis, failure
Adhesive small bowel obstruction
TPN-associated cholestasis
Short bowel syndrome, malabsorption
Sepsis, cardiopulmonary failure
Intraventricular hemorrhage

Intestinal stricture formation following NEC, whether managed operatively or nonoperatively, is common. This consequence usually results from a normal host inflammatory response to transmural intestinal injury. The degree of fibrosis and subsequent stricture formation are clearly related to the severity and extent of disease. Less frequently, mesenteric vascular compromise secondary to an intra-abdominal adhesion may lead to stricture formation. Although stricture can develop anywhere in the gastrointestinal tract involved with NEC, a higher rate of demonstrable stricture is observed in the left colon, occurring in as many as 36% of medically treated infants.⁷⁵ Routine contrast enema 4 to 6 weeks after clinical resolution of NEC treated operatively or nonoperatively has been advocated in some institutions. Symptomatic strictures generally require segmental resection with anastomosis, although fluoroscopically guided balloon catheter dilatation has been reported.

Overall survival rates for infants with NEC have improved significantly over the past three decades and are currently about 60% to 80% for both operative and nonoperative groups.⁷⁶ The observed improvement in survival is thought to reflect improved neonatal intensive care, the use of TPN, and early, aggressive treatment for suspected NEC. Most neonatal intensive care units initiate aggressive medical treatment in any infant with suspected NEC. Whether surgical interventions such as resection with primary anastomosis or limited primary peritoneal drainage can improve morbidity and mortality in these critically ill infants remains to be fully determined. Long-term outcome for NEC survivors generally reflects associated problems of prematurity. In particular, many of these infants have persisting neurodevelopmental, ophthalmologic, and pulmonary disease, but morbidity from the gastrointestinal system generally is limited to infants with short-gut syndrome following extensive bowel resection. These infants present complex ethical and management issues beyond the scope of this review. Most NEC survivors (75%) enjoy a good to excellent quality of life, suggesting that the treatment cost relative to the potential benefit for these infants is worthwhile.⁷⁷

Meconium Ileus

Meconium ileus is a descriptive term for small bowel obstruction in a newborn infant with cystic fibrosis (CF). About 10% to 20% of infants with CF initially present with meconium ileus. A review of CF is useful to understand the pathophysiology and treatment of meconium ileus.

CF is the most common fatal hereditary disease in Europe and North America. It is an autosomal recessive disorder found with a heterozygous carrier incidence rate of 1 in 20 to 25 in white populations. The estimated incidence rate of homozygous gene expression and phenotypic manifestation of CF is about 1 in 2,000 to 2,500 in this population.⁷⁸ The CF gene has been cloned and the single most common mutation characterized.^{79,80} The most common point mutation is a three-base-pair deletion found in 70% to 75% of the carrier population. This mutation leads to deletion of a phenylalanine residue in amino acid position 508 of the CF transmembrane conductance regulator (*CFTR*) gene. In addition, there are about 200 more infrequent mutations of the *CFTR* gene that lead to clinical CF. The molecular heterogeneity of *CFTR* gene mutations produces practical implications in the development and use of carrier screening tests in the general population. Currently, widespread use of molecular genetic screening tests in the general population to identify asymptomatic carriers and at-risk couples without a family history of CF is not recommended; there are significant technical, ethical, and social issues that must be prospectively addressed.⁸¹ Screening of at-risk couples with a family history of CF is recommended, however, and in this setting, carrier discovery approaches 100% so that appropriate genetic counseling can be provided.

Molecular genetic screening also should be offered to parents and infants with clinically suspected CF as well as asymptomatic infants born to at-risk couples. This approach allows rapid identification and confirmation of virtually all infants homozygous for CF.

Pathophysiology. The clinical manifestations of CF are caused by an epithelial electrolyte transport defect that results in impermeability to the chloride (Cl^-) ion.⁸² The epithelial defect occurs in apocrine sweat glands and the tracheobronchial tree as well as the pancreas, gastrointestinal tract, and liver. In sweat glands, failure of normal Cl^- ion reabsorption following beta-adrenergic stimulation leads to an obligate sodium chloride loss despite a normal adenosine triphosphate (ATP)-dependent sodium-potassium pump. This mechanism is the basis for the traditional diagnostic *sweat chloride test*.

Reduction of Cl^- permeability in the tracheobronchial tree leads to diminished secretion volume as well as increased absorption of sodium chloride. As a result, airway secretions in CF patients are low in volume and particularly viscous. Because of the tenacious nature of the airway secretions, airway clearance is impaired, which leads to chronic, recurrent infection with bronchitis and pneumonia. As the disease advances, bronchiectasis and progressive pulmonary parenchymal destruction ensues. Recurrent pulmonary bacterial infection is common, and airway colonization by *P. aeruginosa* is predictable. Chronic pulmonary disease accounts for more than 90% of the deaths in advanced CF, with a mean life expectancy approaching 30 years.

Pancreatic exocrine function is also affected by impaired Cl^- permeability. Pancreatic duct obstruction resulting from inspissated viscous secretion is followed by glandular autolysis, acinar atrophy, and pancreatic fibrosis. Pancreatic exocrine insufficiency is a classic early clinical feature of CF and is thought to account for some of the gastrointestinal manifestations of the disease. In particular, the deficiency of pancreatic proteinases, impaired chloride permeability, and abnormal epithelial mucous secretion lead to meconium ileus in the newborn, characterized by abnormally thick and viscid, protein-laden meconium that causes mechanical gastrointestinal obstruction. The obstruction is usually observed in the terminal ileum just proximal to the ileocecal valve (Fig. 107.22). Infants with meconium ileus have small pellets, or concretions, of pale, nonbilious meconium in the terminal ileum with a distal microcolon. Proximal to the obstruction, the meconium is variably mixed with gas and often is thick and tarry in consistency. The bowel containing the thick meconium is often grossly distended and thickened. Microscopically, the muscularis is hypertrophied; distended mucous glands with prominent goblet cells may be present. The most proximal jejunum is typically normal.

In utero events such as proximal volvulus of the dilated segment of ileum, perforation from distention, or atresia occur in approximately one third to one half of fetuses with meconium ileus. These clinical entities are characterized together as *complicated meconium ileus*. A classic clinical presentation of complicated meconium ileus is in utero intestinal perforation with sterile meconium peritonitis and formation of a calcified pseudocyst (Fig. 107.23). Gastrointestinal conditions presenting later in life occur in 10% of children with CF and include acute appendicitis, recurrent rectal prolapse, and intussusception. These conditions reflect abnormal transit of thick, inspissated stool causing proximal distention or obstruction of the bowel lumen. Small bowel obstruction in CF outside the neonatal period was historically called *meconium ileus equivalent*, and is now termed *distal intestinal obstruction syndrome* (DIOS). Treatment of DIOS is similar to initial nonoperative management of uncomplicated meconium ileus in the newborn discussed later. Prevention of DIOS relies on conscientious pancreatic enzyme replacement. Finally, children with CF are at risk of cholestasis secondary to obstruction of small intrahep-

FIGURE 107.22. Meconium ileus causing obstruction of the terminal ileum from abnormally thick, inspissated meconium.

atic bile ducts. Chronic hepatic inflammation can occur with subsequent fibrosis and cirrhosis, causing hepatic failure and portal hypertension in approximately 5% of CF patients.

Diagnostic Evaluation. In nearly all newborns with CF, the diagnosis is clinically apparent by the presence of meconium ileus, a family history of CF in a sibling, or a positive newborn screening test. Laboratory confirmation of *CFTR* gene dysfunction is performed in several ways. The historical standard for detection of CF has been analysis of the sodium chloride content of the sweat. The most commonly used and reliable technique uses pilocarpine iontophoresis, with positive sweat test results showing sodium and chloride concentrations exceeding 60 mEq/L.⁸³ This test is less useful during the first 4 to 6 weeks of age because normal neonates do not reliably conserve sodium chloride in sweat. Generally, abnormal *CFTR* gene is documented by two elevated sweat chloride tests obtained on separate days. With the emergence of genetic technology capable of providing accurate assessment of *CFTR* gene mutations, the sweat test is now largely used to provide clinical confirmation of *CFTR* gene dysfunction along with molecular diagnosis of CF.

Clinical Presentation. With routine prenatal ultrasound practices along with selected fetal DNA screening, the prenatal diagnosis of CF or meconium ileus is feasible, potentially allowing for improved management of anticipated clinical problems following delivery.⁸⁴ Initial signs of meconium ileus include neonatal bowel obstruction with abdominal distention, bilious emesis, and failure to pass meconium. On examination, the neonate may have palpable loops of meconium-filled intestine with a texture on palpation described as “doughy.” Similar to other causes of proximal neonatal intestinal obstruction, rectal examination and evaluation of the meconium typically reveals clear white mucus or thick gray meconium. In utero intestinal perforation with pseudocyst formation in complicated meconium ileus may cause a palpable abdominal mass that is not particularly tender. On plain films or ultrasound, calcification is visible in the pseudocyst wall. In contrast, volvulus or intestinal perforation secondary to meconium ileus following birth generally results in diffuse peritonitis and sepsis. Intestinal atresia may also be seen as a consequence of complicated meconium ileus.

FIGURE 107.23. A: Plain-film radiograph of calcified pseudocyst in complicated meconium ileus. B: In utero ultrasound demonstrating calcified pseudocyst.

Diagnosis. Abdominal plain films may be diagnostic in meconium ileus, demonstrating multiple, distended loops of bowel (Fig. 107.24A). Fluid- or meconium-filled loops of bowel mixed with gas give a characteristic “soap bubble” or “ground glass” appearance. Classic air–fluid levels seen in other causes of intestinal obstruction are not expected because of the tenacious, sticky intraluminal meconium. The presence of intraperitoneal calcifications or a calcified cyst is consistent with prenatal intestinal perforation of sterile meconium.

A contrast enema is useful in the evaluation and treatment of simple meconium ileus. This study usually demonstrates an unused but functionally normal microcolon (Fig. 107.24B).

Reflux of contrast into the terminal ileum may confirm the presence of inspissated meconium pellets. In conjunction with a family history and plain films, this finding is sufficient evidence to confirm the diagnosis of neonatal meconium ileus. Upper gastrointestinal contrast studies are generally unnecessary and may complicate further therapeutic efforts.

Treatment

Nonoperative. Nonoperative management of simple meconium ileus is achieved in about 60% to 70% of newborns. Once the diagnosis of meconium ileus is confirmed, the initial

FIGURE 107.24. A: Plain radiograph of neonate with meconium ileus. B: Contrast enema in an infant with meconium ileus demonstrating an unused but intrinsically normal microcolon.

treatment of choice is to perform retrograde irrigation of the terminal ileum with one of several solutions designed to dissipate the obstructing meconium. In the United States, several different enema techniques and various contrast media have been described, including normal saline, hyperosmolar contrast agents, and dilute N-acetylcysteine. Initially, it was believed that using hyperosmolar contrast material was necessary to create an osmolar gradient. The resultant influx of fluid into the intestinal lumen was thought to solubilize the inspissated meconium. Recent data suggest that successful meconium clearance is not necessarily related to the osmolality of the contrast agent; however, a significantly higher overall success rate is reported with the use of water-soluble x-ray contrast (sodium and meglumine amidotrizoate) and the use of other solubilizing agents such as Tween-80 and N-acetylcysteine.⁸⁵ As long as clinical progress is being made, sequential enemas may be required to disimpact the inspissated meconium from the terminal ileum. In similar fashion, children and older patients presenting with DIOS are treated with retrograde enemas until the obstruction resolves. The distinct advantage of this treatment approach is the avoidance of general anesthesia and exploratory laparotomy. Reported complications with this approach include rare intestinal perforation, intestinal mucosal injury, and persistent obstruction resulting from meconium concretions.

Operative. The major indications for operative intervention are either failure to clear the obstruction by retrograde enema or complicated meconium ileus with cyst formation, volvulus, atresia, or perforation. For simple meconium ileus with persistent obstruction despite contrast enemas, the operative goals are meconium disimpaction from the ileum and evacuation of the remaining stool from the small intestine. These steps can be accomplished by either milking the meconium downstream into the colon or solubilizing the meconium by transmural needle instillation of irrigant. However, enterotomy or enterostomy and direct irrigation of the bowel lumen are usually required to completely clear the inspissated meconium. Simple closure of the enterotomy is preferred, but segmental resection may be required if marginal or compromised intestine is found. End-to-end anastomosis is the appropriate reconstruction technique following segmental bowel resection. A temporary enterostomy may be required, and several historical techniques have been described. Another surgical option is the placement of a T-tube into the ileum for continued irrigation with dilute N-acetylcysteine. Following clearance of meconium from the intestine and the return of bowel function, the T-tube can be safely and simply removed.⁸⁶

Complicated meconium ileus occurs in about one third of patients. The surgical management of this entity is individualized. Intestinal atresia is not uncommon in meconium ileus, and the entire length of the intestine must be inspected for patency. When possible, resection of nonviable, stenotic, or perforated intestine is performed with immediate reconstruction via primary anastomosis. Patency of the downstream bowel must be confirmed to prevent anastomotic leak resulting from distal obstruction. If the infant is critically ill or has diffuse peritonitis, a safe primary anastomosis may not be possible and a diverting enterostomy is required. Stoma closure may be performed promptly after resolution of peritonitis and inflammation.

Postoperative Care and Results. If the meconium has been successfully cleared without opening the intestine, dilute N-acetylcysteine may be given through the nasogastric tube or by enema. Alternatively, if a T-tube has been placed, dilute N-acetylcysteine or other irrigant can be used directly into the ileum. These efforts are aimed at keeping the meconium soluble and preventing recurrent ileal obstruction. Following return of bowel function, enteral feeding using breast milk or an elemental formula is started along with oral pancreatic enzyme replacement. Vigilant pulmonary therapy is routine and includes mucolytics and

antibiotics when indicated. Nutritional assessment and support are essential in long-term management.

Successful nonoperative management of simple meconium ileus historically was associated with a more favorable outcome; however, the operative mortality rates of infants with meconium ileus have improved dramatically over the past several decades, and current short-term operative survival rates of 70% to 100% are reported.^{87,88} Long-term survival following meconium ileus is generally determined by the course of the underlying pulmonary disease. Contemporary management of CF has produced a mean survival age that approaches 30 years in most centers. With the exception of the development of portal hypertension in about 5% of patients, intestinal manifestations of the CF are treatable. Future medical and surgical efforts to improve the long-term outcome in these patients include direct replacement of the diseased pulmonary system by lung transplantation, manipulation of the epithelial chloride transport defect with pharmacologic agents, and gene therapy directed at *CFTR* gene transfer into respiratory epithelial cells.

Meconium Plug Syndrome

Meconium plug syndrome is characterized by functional obstruction of the colon or rectum by a meconium plug. It affects both normal and premature infants with immature gastrointestinal motility and must be differentiated from other causes of neonatal intestinal obstruction. Unlike meconium ileus, in meconium plug syndrome the colon is of normal caliber and the meconium is not inspissated. The infant's symptoms within the first few days of life are abdominal distention and bilious emesis. Spontaneous passage of meconium is often absent. On examination, the infant is normal with a patent anus and a distended abdomen. Digital rectal examination may deliver the meconium plug. Plain films of the abdomen demonstrate dilated loops of bowel consistent with distal bowel obstruction. The diagnosis is confirmed by contrast enema, which is also therapeutic in helping the meconium plug pass. The meconium plug is followed by bile-stained meconium of normal consistency. It is important that, although the vast majority of these infants are normal, a few have Hirschsprung disease or CF. Therefore, infants presenting with meconium plug syndrome should undergo routine rectal suction biopsy and have CF screening tests performed.

Malrotation

Embryology. Normal midgut fixation requires sequential growth, elongation, and rotation of the intestine beginning as early as week 5 of gestation as illustrated in Figure 107.25. Three distinct events occur during normal midgut fixation. The first stage involves herniation of the primary midgut loop into the base of the umbilical cord, where it remains until week 10 of gestation. The axis of the midgut loop is the superior mesenteric artery (SMA), with the omphalomesenteric duct at the apex of the midgut loop. The midgut loop rotates 180 degrees counterclockwise so that the proximal half passes posterior to the SMA. The proximal portion gives rise to the proximal duodenum, which lies to the right of midline. A portion of this segment becomes the third and fourth portions of the duodenum. The distal duodenum is normally fixed to the left of the aorta at the ligament of Treitz, having rotated 270 degrees counterclockwise from its original position. The jejunoileal segment undergoes dramatic elongation, forming about six primary intestinal loops. The distal midgut loop gives rise to the cecum and the right colon, which also undergoes growth and elongation with concomitant rotation 270 degrees counterclockwise. Therefore, the cecum is initially positioned to the left, then anterior, and finally to the right of the SMA before reaching its final location.⁸⁹

FIGURE 107.25. Normal midgut rotation is shown with appropriate positioning of the stomach, duodenum, small intestine, and cecum from the fifth gestational week (A) through completion by the 12th week (E).

Reduction of the extracoelomic gut is the second stage of midgut development and fixation, occurring between weeks 10 and 12 of gestation. By this time, the duodenojejunal junction has passed posterior to the SMA and the midgut has rotated 180 degrees counterclockwise; however, the small intestine initially remains to the right side of midline, and the cecum and ascending colon are anterior to the SMA after return of the gut into the abdomen. Many common abnormalities of intestinal fixation occur as a result of arrested development during this 2-week period.

The final stage of midgut development is fixation of the intestine to the posterior body wall, occurring after week 12 of gestation. Cecal descent occurs at this time. Normal points of fixation include the cecum in the right iliac fossa and the duodenojejunal junction at the ligament of Treitz just to the left of the aorta and anterior to the left renal vein (Fig. 107.26). Therefore, the normal intestinal mesentery is fixed with a broad base extending from the ligament of Treitz to the cecum. This broad-based mesenteric attachment prevents volvulus from occurring. In contrast, in disorders of intestinal rotation,

the base of the mesentery is neither fixed nor broad, placing the entire midgut at risk for volvulus.

Anatomy. The normal sequence required for intestinal positioning and fixation can be interrupted at any developmental stage, producing a diverse spectrum of rotational abnormalities. Some neonatal surgical conditions are nearly always associated with abnormal intestinal rotation or fixation resulting from displacement of the midgut from the abdominal cavity during embryologic development. These anomalies include omphalocele, gastroschisis, and congenital diaphragmatic hernia. The term *malrotation* has been applied generically to describe disorders of intestinal rotation and fixation, although specific definitions of the more commonly encountered lesions are provided in the following sections.

Nonrotation. This common anomaly is characterized by inadequate counterclockwise rotation of the midgut around the SMA. Instead of the normal 270-degree arc, rotation is either absent or arrested before exceeding 90 degrees (Fig. 107.27). The small

FIGURE 107.26. Normal oblique fixation of the midgut mesentery at the ligament of Treitz and in the right lower quadrant. The blue portions of the colon are extraperitoneal.

intestine resides on the right side of midline, the colon resides on the left, and the cecum is anterior and near the midline. The duodenojejunal junction is to the right of midline and more caudal and anterior in position. Nonrotation carries a significant clinical risk of midgut volvulus because the mesenteric vascular pedicle is narrow. Duodenal obstruction also may occur as a result of

FIGURE 107.27. Nonrotation. The proximal segment of the small intestine resides on the right side of the abdomen, and the distal segment (colon) is on the left. Neither has rotated normally.

FIGURE 107.28. Incomplete rotation. The proximal segment has failed to rotate and is on the right. The distal segment has rotated to reside anterior to the duodenum so that cecal bands to the posterior abdominal wall may compress and obstruct the duodenum.

peritoneal attachments known as *Ladd bands*. These peritoneal bands fix the cecum to the posterior body wall by passing anterior and lateral to the distal duodenum.

Mixed or Incomplete Rotation. This rotational abnormality is characterized by arrest of the normal rotation at or near 180 degrees rather than the normal 270 degrees (Fig. 107.28). Instead of rotating posterior and to the left of the SMA, incomplete or arrested rotation of the prearterial segment leaves the duodenojejunal junction to the right of midline. The cecum also does not complete its counterclockwise passage anterior to the SMA; it usually resides in the upper abdomen just to the left of the SMA. Similar to nonrotation, fixation of the cecum to the posterior body wall by Ladd bands places the duodenum at risk for compression or obstruction. Additionally, the SMA pedicle is narrow and places the midgut at risk for volvulus.

Mesocolic Hernias. Mesocolic hernias are rare but important anomalies characterized by failure of fixation of either the right or left mesocolon to the posterior body wall. Small bowel can become entrapped in the resulting potential cavities on either side of the abdomen. A right-sided mesocolic defect (paraduodenal hernia) is associated with nonrotation of the proximal midgut segment. Small bowel entrapment posterior to the right colon and cecum may occur. Similar entrapment of small bowel may occur from an incompletely fixed left mesocolon but is associated with normal colonic and cecal position. Entrapped small bowel in a left mesocolic hernia usually is contained within a hernia sac with the neck composed of the inferior mesenteric vein and peritoneal bands extending to the posterior body wall. Both left and right mesocolic hernias carry the potential risks of obstruction, incarceration, and strangulation of bowel.

Clinical Presentation. Abnormalities of intestinal rotation are estimated to be present in about 1% of the population. Most persons with intestinal rotational anomalies are clinically asymptomatic; therefore, some children are found to have malrotation incidentally by upper gastrointestinal contrast studies conducted for other reasons. Symptomatic malrotation usually is encountered clinically in the setting of duodenal obstruction

or midgut volvulus. Duodenal obstruction may occur as a result of Ladd bands fixing the abnormally positioned cecum to the posterior body wall. These peritoneal bands cause duodenal obstruction by extrinsic compression. Children with symptomatic duodenal obstruction typically present with bilious emesis and distention of the stomach and proximal duodenum. Similar to proximal neonatal intestinal obstruction, newborn infants may present with bilious emesis without abdominal distention secondary to partial duodenal obstruction. A paucity of small bowel gas may be seen on plain abdominal films.

A potential consequence of intestinal malrotation is midgut volvulus. Midgut volvulus should be considered in any infant or child presenting with bilious emesis. The clinical outcome of midgut volvulus is time dependent, which is the fundamental reason that signs and symptoms of acute intestinal obstruction in an infant or child must be pursued aggressively until a clear diagnosis is made. The devastating, life-threatening consequence of midgut volvulus is vascular insufficiency, gut ischemia, and, if untreated, infarction of the entire bowel supplied by the SMA. The initial symptoms may be subtle and limited to feeding intolerance, abdominal pain, and irritability followed by bilious emesis. Guaiac-positive stool from mucosal injury is a common early finding. Late findings include progres-

sive abdominal distention, hematemesis, and hypotension. Metabolic acidosis, coagulopathy, and shock may become prominent clinical features. If unrecognized or left untreated, transmural necrosis of the entire midgut will occur.

At least 50% to 75% of intestinal rotational abnormalities are discovered within the first week to month of life, and about 90% occur in children younger than 1 year.^{90,91} Symptomatic infants and children require emergent surgical exploration and correction. Older children and adults initially may present with acute volvulus but also may have a history of vague symptoms of episodic intestinal obstruction and chronic abdominal pain. It is essential to recognize that, regardless of age or chronicity of symptoms, midgut volvulus from malrotation occurs in a completely unpredictable manner.⁹² Therefore, it is generally recommended that patients with incidentally discovered, asymptomatic malrotation undergo operative management to reduce the risk of volvulus.

Diagnosis. As with other forms of neonatal intestinal obstruction, the diagnostic evaluation begins with a plain abdominal radiograph. Classic findings with malrotation include gastric and proximal duodenal distention with a paucity or absence of distal small bowel gas (Fig. 107.29A). The plain film alone may

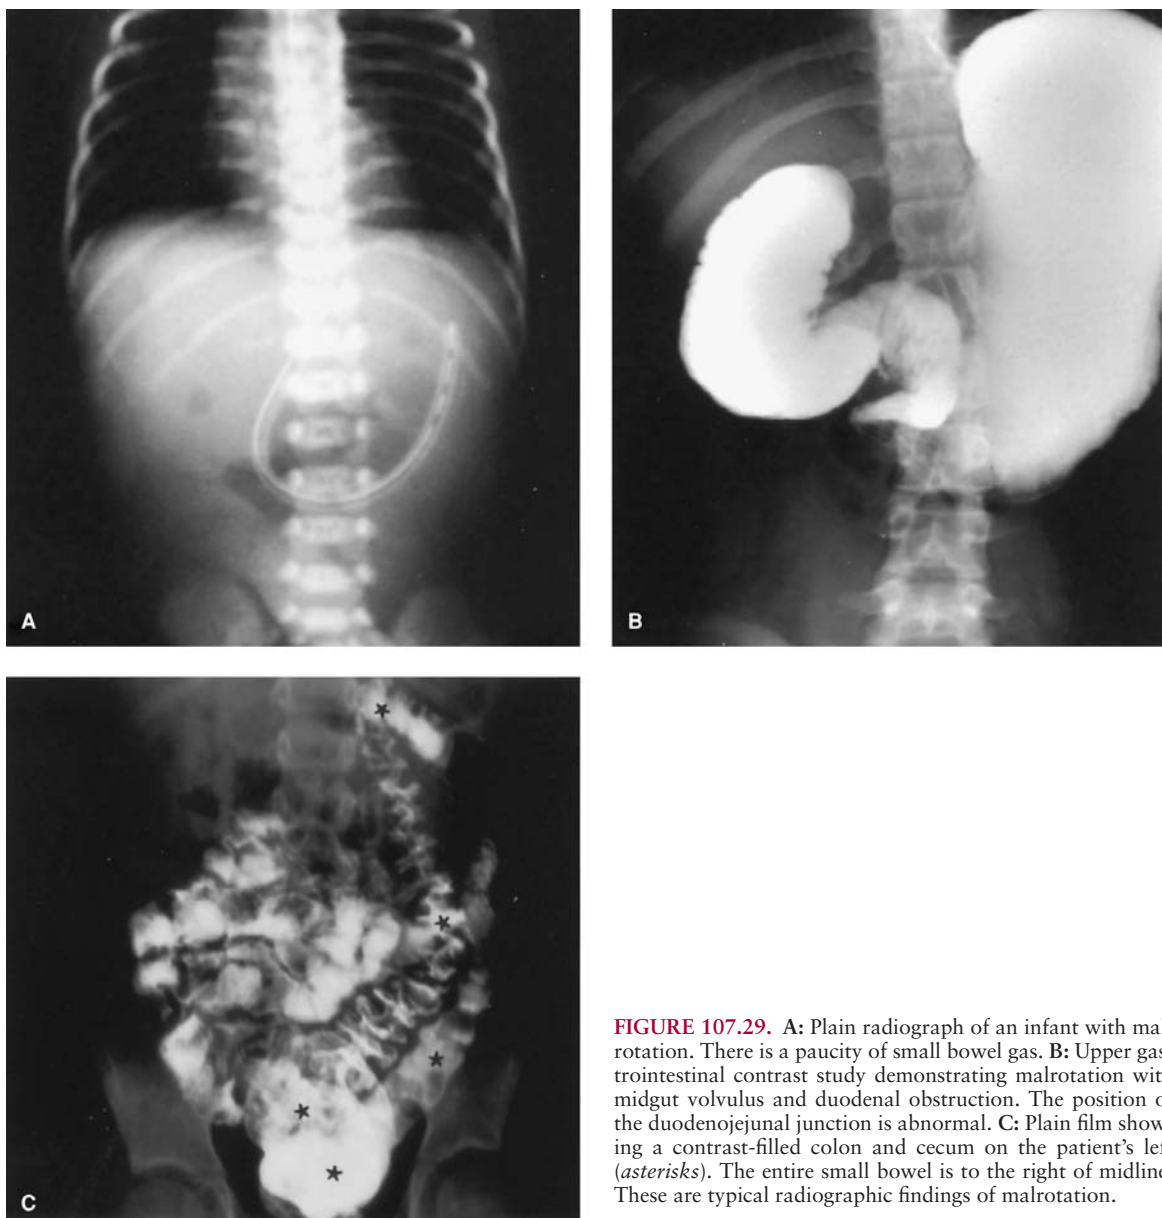

FIGURE 107.29. A: Plain radiograph of an infant with malrotation. There is a paucity of small bowel gas. B: Upper gastrointestinal contrast study demonstrating malrotation with midgut volvulus and duodenal obstruction. The position of the duodenojejunal junction is abnormal. C: Plain film showing a contrast-filled colon and cecum on the patient's left (asterisks). The entire small bowel is to the right of midline. These are typical radiographic findings of malrotation.

not differentiate malrotation from duodenal atresia or stenosis. In most cases of suspected duodenal obstruction with concern of malrotation, an upper gastrointestinal series is a conclusive imaging study (Fig. 107.29B). Malrotation with volvulus typically produces incomplete duodenal obstruction with a corkscrew or coiled appearance in the distal duodenum. Extrinsic compression of the duodenum by Ladd bands may be visible on contrast study. Duodenal atresia and stenosis may occur anywhere within the duodenum but tend to be more proximal. Complete absence of small bowel gas is typical of duodenal atresia, whereas diminished but discernable distal gas is characteristic of duodenal stenosis or malrotation with volvulus.

Other radiographic findings in malrotation include incorrect position of the duodenojejunal junction, particularly to the right of midline. Failure to achieve normal cephalad and posterior fixation is typical in malrotation and may be best appreciated on lateral views. The small bowel resides in the right side of the abdomen, the colon and cecum on the left (Fig. 107.29C). In a symptomatic infant or child, radiographic evidence of malrotation alone is enough to warrant emergent exploration. A contrast enema is helpful in the evaluation of neonatal intestinal obstruction, although it may not be the initial study of choice if malrotation is suspected. The classic finding on contrast enema for malrotation is cecal malposition, usually in the left abdomen or near the midline. Finally, the relative position of the SMA to the superior mesenteric vein may be assessed by ultrasound. Normally, the superior mesenteric vein is to the right of the SMA on transverse sonograms. Abnormal position of the superior mesenteric vein either ventral or to the left of the SMA is associated with malrotation.⁹³

Treatment. The management of bowel obstruction from malrotation or an internal hernia is operative. Initial assessment, resuscitation, and preoperative preparation in a symptomatic newborn should be conducted simultaneously so that confirmation of malrotation can be followed immediately by laparotomy. Urgent laparotomy is required to reduce the ischemic injury to the intestine. Shock, if present, must be treated aggressively by ensuring adequate gas exchange and establishing restoration of intravascular volume prior to the induction of general anesthesia. Volvulus with complete infarction of the midgut, if not immediately lethal, is survivable only with enterectomy followed by permanent or long-term TPN support. In older, asymptomatic children with incidentally discovered malrotation, operative repair remains controversial. Given the devastating consequences of midgut volvulus, however, elective surgical correction appears warranted in most asymptomatic individuals as well.

Operative repair of malrotation is performed by the Ladd procedure.⁹⁴ The first objective is to relieve the midgut volvulus, if present. This is accomplished by delivery and detorsion of the affected midgut, usually in a counterclockwise direction. Recurrent volvulus is prevented by broadening the base of the mesenteric vascular pedicle by dividing the peritoneal bands that tether the cecum, small bowel mesentery, mesocolon, and duodenum around the base of the SMA (Fig. 107.30). Once completed, the mesentery and mesocolon open widely and the mesenteric pedicle is at low risk for recurrent volvulus.

The second objective of the Ladd procedure is to divide the abnormal peritoneal attachments between the cecum and the abdominal wall. A modified Kocher maneuver involving meticulous and complete mobilization of the entire duodenum with division of all anterior, lateral, and posterior attachments is performed. Duodenal and distal small bowel patency should be demonstrated using intraluminal air or saline because synchronous intestinal webs and atresia have been reported. An appendectomy is performed to eliminate potential confusion from acute appendicitis developing in an abnormally positioned appendix. Performance of a laparoscopic Ladd procedure has been demonstrated to be feasible and may help to

reduce time to enteral feeding and hospital length of stay; however, the long-term efficacy of this approach has been debated.⁹⁵ Fixation of the mesentery by cecal or duodenal plication to the body wall has been abandoned for lack of data supporting efficacy. Postoperative small bowel obstruction secondary to adhesions is reported in about 10% of patients.

Volvulus with intestinal necrosis is treated by preserving as much bowel length as possible. If bowel viability is unclear during initial exploration, a second-look procedure may be helpful to delineate reversible from irreversible injury. The management of nonviable bowel from volvulus is not different from other situations in which intestinal necrosis is encountered, and clinical decisions regarding resection and anastomosis are individualized. In situations where the entire small intestine is lost and long-term survival doubtful, treatment decisions must be made with the family.

Surgical management of right mesocolic hernia is directed at dividing the lateral peritoneal attachments of the cecum and right colon to eliminate the hernia. In addition, given the associated nonrotation of the proximal bowel, the vascular pedicle should be broadened as much as possible. Left mesocolic hernia is treated by mobilization of the inferior mesenteric vein, reduction of the small bowel from the hernia sac, and closure of the neck of the hernia sac to eliminate the potential space.

Results and Complications. Results following surgical correction of intestinal rotational abnormalities should be excellent, and life expectancy should be normal in the absence of intestinal necrosis. Recurrent volvulus and recurrent duodenal obstruction are distinctly unusual if the initial procedure is technically complete. Adhesive small bowel obstruction following the Ladd procedure is reported in 1% to 10% of patients. Long-term outcome is obviously less favorable in patients with intestinal necrosis at the time of exploration.

Congenital Aganglionosis (Hirschsprung Disease)

5 Embryology. Congenital aganglionosis of the intestine (Hirschsprung disease) is characterized by the absence of intestinal ganglion cells. The pathogenesis of aganglionosis remains unknown. In normal development, neuroblasts derived from neural crest precursors become evident by week 5 of gestation. The neuroblasts begin maturation and caudal migration along with vagal nerve fibers. The initial caudal migration in an intermuscular plane is followed by intramural dispersal into both superficial and deep submucosal nerve plexuses. Ultimately, the neuroblasts give rise to the ganglion cells of the myenteric nervous system, with functional maturation continuing well into infancy. The orderly migration pathway of myenteric innervation has been documented in human embryos; normally, ganglion cells can be identified in the esophagus at week 6 of gestation, in the transverse colon at week 8 of gestation, and in the rectum by week 12 of gestation.⁹⁶

Anatomy. Hirschsprung disease is characterized by a lack of ganglion cells in the distal intestine. The length of aganglionosis is variable but most commonly involves the distal rectosigmoid colon in 75% to 80% of affected infants. In about 5% of cases, the transition zone between the normal, proximal bowel and the distal, aganglionic segment occurs in the small intestine.⁹⁷ Discontinuous aganglionosis has been reported but should be considered distinctly unusual. Therefore, in virtually all cases, the aganglionic intestinal segment is continuous with the distal rectum to the anal verge and also includes the internal sphincter. Because of this distribution, the pathogenesis of congenital aganglionosis is often attributed to failure of neuroblast migration. The characteristic lesion in the distal bowel is the aganglionosis in the intermuscular and submucosal

FIGURE 107.30. Correction of malrotation with volvulus. **A and B:** Detorsion of midgut. **C and D:** Division of peritoneal attachments (Ladd bands) of cecum to abdominal cavity.

plexuses. Large, hypertrophied, nonmyelinated nerve fibers are present within the muscularis mucosa, lamina propria, submucosa, and Auerbach intermuscular plexus. Both adrenergic and cholinergic fibers are prominent in the aganglionic segment, and acetylcholinesterase staining is useful diagnostically. Abnormalities in the peptidergic nervous system, including vasoactive intestinal peptide, substance P, and neurotensin immunoreactive fibers, also are described in the aganglionic bowel segment.⁹⁸ Deficient neuronal nitric oxide synthase mRNA and subsequent decreased local nitric oxide synthase activity in the aganglionic bowel have also been described.⁹⁹ These experimental data are consistent with the concept that a defect in nitric oxide-mediated smooth-muscle relaxation may account for some of the characteristic clinical features of Hirschsprung disease.

The transition zone between the normal proximal bowel and the aganglionic distal bowel is distinguished grossly by distention of the proximal bowel with histologic evidence of muscular hypertrophy. The transition zone often becomes evident to

direct inspection or on contrast enema during the first few weeks of life as functional obstruction leads to progressive proximal dilatation. On gross inspection, the transition zone may appear as a short funnel or cone-shaped colonic segment. The discrepancy in bowel lumen diameter is somewhat age dependent and may be subtle in a newborn or in a child with total colonic aganglionosis. Therefore, it may be difficult for the surgeon or radiologist to define the exact transition zone site based on gross inspection or contrast enema. Gross examination alone is not sufficient for surgical decision making, and histologic confirmation of the level of ganglion cell transition is required. Given the continuous nature of aganglionosis, a rectal biopsy performed 1 to 1.5 cm above the dentate line demonstrating ganglion cells effectively excludes Hirschsprung disease.

Neuronal intestinal dysplasia is a clinically described entity similar to or associated with Hirschsprung disease.^{100,101} Despite the presence of ganglion cells, dysplastic changes in the myenteric nervous system affect bowel motility in similar fashion to aganglionosis. Clinical presentation and treatment

are similar to those of classic Hirschsprung disease. There is considerable controversy regarding neuronal intestinal dysplasia, but it is reasonable to suggest that this represents an entity within the spectrum of abnormalities found in the intestinal myenteric nervous system.

Pathophysiology. Normal intestinal motility depends on coordinated propagation of segmental contraction waves immediately preceded by relaxation of the enteric smooth muscle. Patients with Hirschsprung disease lack a functional myenteric nervous system in the aganglionic segment; therefore, both propulsion and reflexive relaxation are disordered or absent in the distal bowel. Loss of neuronal nitric oxide synthase activity appears to play an important role. The internal sphincter is aganglionic and lacks the normal reflexive relaxation following rectal distention. In fact, patients with Hirschsprung disease may exhibit a paradoxical increase in sphincter tone in response to rectal distention. The functional result is tonic contraction of the aganglionic segment of bowel with ineffective peristalsis. Clinically, this presents as incomplete distal intestinal obstruction in the newborn or as chronic constipation in the older child or adult.

Hirschsprung disease has been associated with mutations in at least three specific genes: the *RET* protooncogene, the endothelin B receptor (*EDNRB*) gene,¹⁰² and the endothelin 3 (*EDN3*) gene. Additionally, several other candidate genes are under investigation. In mice, natural and in vitro induced mutations affecting the *RET*, *EDNRB*, and *EDN3* genes generate intestinal aganglionosis identical to Hirschsprung disease.^{103,104} Although widely accepted, it is still unknown whether the primary event in aganglionosis is failure of neuroblast migration to the distal bowel. Alternatively, ineffective microenvironmental support of neuroblasts that have already migrated may fail to promote normal neuroblast development and survival.¹⁰⁵

Clinical Features

Incidence and Associations. The incidence rate of Hirschsprung disease is estimated at 1 per 5,000 live births with a marked male-to-female (4:1) preponderance. Most cases are sporadic, but long-segment, total colonic aganglionosis and female gender are strongly associated with familial inheritance. Genetic chromosomal analysis suggests that multiple loci may be involved, including chromosomes 13q22, 21q22, and 10q, among others.¹⁰⁶ Familial Hirschsprung disease has been clearly associated with *RET* protooncogene mutations. From a clinical standpoint, mutations of the *RET* protooncogene are associated with disorders of neural crest development, namely, multiple endocrine neoplasia (MEN) types IIA and IIB as well as familial medullary thyroid carcinoma, and patients with familial Hirschsprung disease associated with *RET* mutation are at risk for the development of medullary thyroid carcinoma.¹⁰⁷ Congenital cardiac defects are present in 2% to 5% of patients with Hirschsprung disease. Other rare congenital anomalies have been reported, but a consistent and important association is a 5% to 15% incidence of trisomy 21.¹⁰⁸ Infants presenting with meconium plug syndrome should undergo rectal suction biopsy to exclude aganglionosis.

Presentation. Most infants with Hirschsprung disease fail to pass meconium within the first 24 to 48 hours of life. Nonspecific signs of neonatal intestinal obstruction (feeding intolerance, abdominal distention, and bilious emesis) may develop. About half of patients with Hirschsprung disease are diagnosed as neonates. Infrequently, older children or adults are diagnosed with aganglionosis during evaluation for chronic constipation. In this setting, symptoms may be minimal to disabling, and parents or patients often develop elaborate strategies to deal with chronic constipation. Abdominal distention is characteristic, and sometimes failure to thrive and malnutrition

may occur. Digital rectal examination may demonstrate spasm, and, in the presence of enterocolitis, forceful expulsion of foul-smelling, liquid stool may occur.

Enterocolitis occurs in about 10% to 30% of infants and children with Hirschsprung disease and may be the presenting clinical manifestation. Enterocolitis associated with Hirschsprung disease has an unknown pathophysiology, but obstructive stasis and bacterial overgrowth are thought to be important factors. *C. difficile* and rotavirus have been implicated as important pathogenic organisms; diagnostic and treatment plans should consider these possibilities. The early presenting symptoms and signs of enterocolitis include fever, abdominal distention, and diarrhea, which may be explosive, foul-smelling, and bloody. Systemic sepsis, transmural intestinal necrosis, and perforation are all possible later findings. The clinical progression can be rapid, with death occurring in as few as 12 to 24 hours if treatment is not initiated. Infants are particularly vulnerable to this complication, and enterocolitis accounts for virtually all mortality directly related to Hirschsprung disease in modern pediatric surgical practice. Infants with known Hirschsprung disease and suspected enterocolitis should be treated aggressively. Initial treatment includes resuscitation, broad-spectrum antibiotics, cessation of feeding, and rectal irrigation. If the enterocolitis does not respond promptly, emergent intestinal decompression with an enterostomy proximal to the transition zone is indicated.

Diagnosis. A high index of suspicion for Hirschsprung disease should be maintained for any newborn infant with abdominal distention failing to pass meconium in 24 to 48 hours. The signs of neonatal intestinal obstruction should lead to a stereotypical workup. In the presence of characteristic findings on history, examination, or radiographic studies, any infant suspected of having Hirschsprung disease should undergo rectal biopsy.

Plain Abdominal Radiographs. Plain-film radiographs of the neonate with Hirschsprung disease are nonspecific and typically demonstrate distended, air-filled loops of bowel throughout the abdomen. It is often difficult to discriminate between small and large intestine on plain films at this age, but the pattern is consistent with distal intestinal obstruction. Older children or adults may have a stool-filled megacolon on plain radiographs. In the presence of enterocolitis, thickened, dilated intestinal loops and pneumatosis intestinalis may be present.

Contrast Enema. When distal neonatal intestinal obstruction is suspected on plain abdominal films, a contrast enema should be performed. With an experienced pediatric radiologist, findings consistent with Hirschsprung disease can be accurately detected in most instances. The classic radiographic finding in Hirschsprung disease is a transition zone (Fig. 107.31A). A definitive transition zone may not be apparent in a neonate because proximal dilatation takes some time to develop. Additionally, infants with short-segment disease or total colonic aganglionosis may not have obvious transition zones on contrast enema. In these instances, a lateral view of the rectum may show abnormal spasm (Fig. 107.31B). Contrast remaining in the rectum more than 24 hours following a study is suggestive of Hirschsprung disease.

Rectal Biopsy. The diagnostic standard for aganglionosis is the rectal biopsy. Several commercially available instruments capable of performing rectal suction biopsies are in widespread use. The rectal suction biopsy can be performed at bedside or in clinic without anesthesia in all newborns and most children up to several months of age. The desire for early diagnosis and the technical simplicity of the procedure allow liberal use of this technique. When applied liberally, the vast majority (85%–90%) of infants undergoing this procedure have normal ganglion cells on biopsy, effectively excluding Hirschsprung

FIGURE 107.31. A: Contrast enema demonstrating a classic rectosigmoid transition zone in Hirschsprung disease. B: Lateral view of rectum illustrates typical distal spasm of rectum. C: Operative photograph of rectosigmoid transition zone.

disease. Using the rectal suction biopsy technique, a biopsy of the mucosa and submucosa is obtained. This is sufficient to establish the diagnosis because ganglion cells are absent from all intramural plexuses in Hirschsprung disease. The biopsy must be taken 1 to 1.5 cm proximal to the dentate line. Complications of infection, perforation, and bleeding with rectal suction biopsy are infrequent. Full-thickness rectal biopsy under general anesthesia is reserved for older children and in infants in whom suction biopsy is inadequate. An experienced pediatric pathologist must read the biopsies for maximal diagnostic accuracy. Evaluation for ganglion cells and the axons of the myenteric neurons is performed (Fig. 107.32), which may be accomplished using conventional hematoxylin-eosin staining or histochemical staining for acetylcholinesterase. Similar histochemical staining for nitric oxide synthase can be performed. These adjunctive techniques are used routinely in some centers and can help to provide additional evidence of Hirschsprung disease rather than simply demonstrating aganglionosis in the biopsy specimen. Diagnostic accuracy for Hirschsprung disease is excellent with a correctly obtained rectal suction biopsy and an experienced pediatric pathologist.¹⁰⁹

Anorectal Manometry. The absence of sphincter relaxation in response to rectal dilatation is consistent with Hirschsprung disease. Because of the relative ease and accuracy of rectal suction biopsy, anorectal manometry is not widely used in the United States for the primary diagnosis of Hirschsprung disease in infancy; however, this is used in some centers around

the world, and when applied carefully with an appropriate transduction probe, accurate manometric diagnosis is achievable in 85% to 90% of cases.

Treatment. Diverting colostomy should be considered for a newborn infant with Hirschsprung disease who has enterocolitis or multiple associated medical problems or anomalies. In the presence of enterocolitis, rectal irrigation and decompression can be an effective temporizing measure while resuscitation and broad-spectrum antibiotics are being instituted. Prompt proximal diversion will be required once the patient has stabilized. In the neonate, one approach following diagnosis is to perform proximal diversion by means of a colostomy (or enterostomy) placed in normal, ganglionated intestine. The diverting colostomy must be proximal to the histologic transition zone, and a series of biopsies examined by frozen section may be necessary to find the correct level for diversion. For classic rectosigmoid disease, a leveling colostomy is placed just proximal to the transition zone. This approach is generally done in two stages, with takedown of the stoma and definitive pull-through operation performed together weeks to months later, typically when the infant reaches 9 to 12 months of age. In older children, definitive pull-through is deferred until the colon has decompressed to relatively normal caliber.

For many infants and children without enterocolitis, a single-stage approach that eliminates the diverting colostomy has been advocated.^{110,111} Despite several different operative techniques in performing a single-stage pull-through, results and outcomes

FIGURE 107.32. A: Normal rectal biopsy with ganglion cells indicated by *arrow* (hematoxylin-eosin). B: Rectal biopsy specimen with aganglionosis (hematoxylin-eosin). Note the characteristic thickened nerve fiber (*arrow*). C: Normal rectal biopsy using acetylcholinesterase histochemical staining. D: Similarly stained specimen from a patient with Hirschsprung disease. Many thickened submucosal nerve fibers stain densely black.

appear nearly equivalent. Definitive repair of Hirschsprung disease with a single operation is desirable from technical and economical standpoints and essentially eliminates the complications associated with neonatal stomas. As with most aspects of pediatric surgery, an increasing experience with laparoscopically assisted, single-stage pull-through operations has been reported.¹¹² The contemporary, laparoscopic single-stage approach in the management of Hirschsprung disease has gained wide acceptance in the pediatric surgical community and is considered by many surgeons as the current standard of care for most infants and children.

Definitive Operations for Hirschsprung Disease. The major goal of operative therapy in the treatment of Hirschsprung disease is

to provide resection or bypass of the distal aganglionic rectum with the performance of a low rectal anastomosis with normally innervated proximal intestine. Numerous definitive procedures have been designed to treat Hirschsprung disease, and a brief description of the principal procedures in use follows. In general, the selection of a procedure depends on a surgeon's individual training and preference rather than compelling differences in outcome.^{113,114}

Duhamel Procedure (Martin Modification). The key elements of the Duhamel procedure are illustrated in Figure 107.33. After minimal pelvic dissection, resection of the aganglionic colon is performed. The aganglionic rectum is left in situ. Normal proximal colon is brought caudad into the retrorectal

FIGURE 107.33. Duhamel procedure (Martin modification). **A:** Blunt retrorectal dissection. **B:** Incision in the posterior wall of the aganglionic rectum. **C:** Retrorectal pull-through after resection of the proximal aganglionic segment. **D:** End-to-side colorectal anastomosis preserving aganglionic rectum (as originally described). **E:** Stapled conversion of anastomosis into an extended side-to-side colorectal anastomosis (Martin modification). **F:** Completed procedure.

space, and a colorectal anastomosis is performed 1 cm above the dentate line. The original operation left the defunctionalized rectal pouch as shown, which proved problematic. The procedure has been modified by Martin to include a longer side-to-side colorectal anastomosis. Advantages of this procedure include its relative technical ease and limited pelvic dissection. Adoption of the stapled anastomosis has simplified this procedure significantly.

Soave Procedure. The Soave procedure is illustrated in Figure 107.34. Following resection of aganglionic colon, an endorectal dissection in the submucosal plane is performed from proximal rectum to anus. The endorectal dissection is started in the extraperitoneal rectum. This dissection is typically much easier than similar dissection for ulcerative colitis given the lack of mucosal inflammation. The dissected rectal mucosal tube is everted through the anus, excised, and normal proximal bowel is pulled through the rectal muscular cuff. The original operation

did not suture the pull-through segment of proximal bowel to the rectum. A formal sutured colorectal anastomosis is now universally performed. Care must be taken to ensure that the pull-through segment is not obstructed by the muscular cuff.

Swenson Procedure. The Swenson procedure is the original definitive procedure for the treatment of Hirschsprung disease. It is somewhat more demanding from a technical standpoint, and, as such, it has been reported to have a slightly higher incidence of postoperative complications. However, long-term outcome in children who undergo a properly performed Swenson procedure is equivalent to other procedures. The basic strategy is outlined in Figure 107.35. The aganglionic segment of colon is resected and a careful, nearly complete extramural dissection of the distal rectum is performed. Care must be taken to avoid inadvertent injury to the seminal vesicles, vas deferens, ureters, and pelvic splanchnic nerves. The dissected rectum is everted through the anus onto the perineum and

FIGURE 107.34. Soave endorectal procedure. **A:** Endorectal dissection initiated. **B:** Endorectal dissection complete. **C:** Eversion of the aganglionic segment and rectal mucosal tube. **D:** Incision of everted rectal tube. **E:** Endorectal pull-through. **F:** Colorectal anastomosis. **G:** Completed procedure.

excised. Normal proximal bowel is pulled through and a colorectal anastomosis is performed.

Laparoscopically Assisted Endorectal Pull-through. A multi-institutional clinical experience with a laparoscopically assisted endorectal pull-through technique for the treatment of

Hirschsprung disease has been reported.¹¹² Potential advantages of this approach include excellent visibility of the distal rectum during dissection, early return of postoperative bowel function, and decreased length of hospital stay. The early results report outcomes similar to the other established procedures. The procedure is reviewed in Figure 107.36. Complete

FIGURE 107.35. Swenson procedure. A: Extramural rectal dissection. B and C: Eversion of aganglionic segment and full-thickness rectum. D: Pull-through of normal, ganglionic bowel. E: Colorectal anastomosis. F: Completed procedure.

transanal excision of the distal aganglionic segment with primary coloanal anastomosis has also been performed for short-segment or typical rectosigmoid aganglionosis as well.

Rectal Myectomy. Resection of a longitudinal strip of the posterior rectal muscular wall has been used for definitive management of ultrashort-segment Hirschsprung disease. This procedure can be performed via transanal approach combined with submucosal dissection or by a posterior sagittal approach. Although controversial, the use of rectal myectomy as a definitive operation for Hirschsprung disease may be considered most useful in the selected older child identified with ultrashort-segment disease.¹¹⁵

Total Colonic Aganglionosis. Total colonic aganglionosis is complex and, fortunately, relatively rare. Several different operative procedures have been described, and treatment must be individualized. The endorectal pull-through with ileoanal anastomosis has been used with good success when most or all of the small bowel is normal. For extensive small bowel agan-

glionosis, an extended side-to-side anastomosis of normally innervated proximal small bowel to the aganglionic colon has been successfully performed. For complete intestinal aganglionosis, extended intestinal myectomy has been described.

Complications and Outcome. Complications resulting from definitive procedures for Hirschsprung disease include anastomotic leak, stricture, pelvic or rectal muscular cuff abscess, intestinal obstruction, and wound infection. These occur with a frequency of 1% to 10% with most experienced pediatric surgeons. Mortality from Hirschsprung disease is distinctly unusual unless enterocolitis is the presenting feature or associated medical problems or anomalies are present.

A unique complication following definitive repair of Hirschsprung disease is postoperative enterocolitis. The clinical presentation and pathogenesis have been discussed, and it remains an important and significant cause of morbidity. The incidence of postoperative enterocolitis ranges from 10% to 30% in most large series. Although rare, Hirschsprung enterocolitis can occur even in the presence of a diverting colostomy.

FIGURE 107.36. Laparoscopically assisted pull-through for Hirschsprung disease. **A:** Sites for operative trocar placement. **B:** Division of colon and rectal mesentery with mobilization of proximal colon. **C:** Circumferential incision in rectal mucosa 5 to 10 mm cephalad to the pectinate line. **D:** Mucosal traction sutures to facilitate further dissection from rectal muscular cuff. **E:** Transanal submucosal dissection is continued cephalad to meet the caudal extent of the transperitoneal rectal dissection. **F:** Circumferential incision of rectal muscular cuff. **G:** Rectal muscular cuff is split posteriorly to accommodate the pull-through segment (the pull-through segment is not shown here to clarify this maneuver). **H:** Rectum and sigmoid colon are pulled through the rectal muscular cuff to the anastomotic site. **I:** Colon is transected at appropriate site with confirmation of ganglion cells by frozen section. **J:** Transanal, end-to-end single layer colorectal anastomosis.

Long-term outcomes appear quite good for all the procedures used, with 80% to 90% of patients maintaining good to excellent bowel function.

OTHER CHILDHOOD GASTROINTESTINAL DISORDERS

This review is limited to relatively common surgical conditions that are either congenital or unique in children. For other surgical conditions that can affect both children and adults, the reader is referred to other chapters in this text.

Infantile Hypertrophic Pyloric Stenosis

Anatomy and Pathophysiology. The pathogenesis of infantile hypertrophic pyloric stenosis is unknown, but data suggest that local deficiency of neuronal nitric oxide synthase in the pylorus may be responsible for the clinical manifestations of the disease.^{116,117} The deficiency of neuronal nitric oxide synthase leads to a lack of nitric oxide-mediated relaxation of smooth muscle and subsequent pyloric obstruction. Luminal narrowing occurs as a result of concentric hypertrophy of the pyloric smooth muscle. Clinically, this presents as progressive gastric outlet obstruction that becomes symptomatic by 2 to 4 weeks of age. The maximal narrowing and clinical symptoms of hypertrophic pyloric stenosis occur between 4 and 8 weeks of age. The hypertrophic pyloric muscle ultimately undergoes gradual involution over a period of weeks to months.

Clinical Presentation. The reported incidence rate of hypertrophic pyloric stenosis is approximately 0.1% to 0.4% among white infants and is slightly lower in the black population. There is a distinct familial predisposition with an approximate 7% incidence rate in children of parents with a history of pyloric stenosis. The incidence rate is about four times higher in males than in females and is higher in first-born infants.¹¹⁸ There is an apparent increased risk of hypertrophic pyloric stenosis in infants receiving oral erythromycin for pertussis prophylaxis.¹¹⁹ Association of pyloric stenosis in infants treated for esophageal atresia and in infants with Smith-Lemli-Opitz syndrome has been reported.¹²⁰

Infants with hypertrophic pyloric stenosis have a history of nonbilious, postprandial emesis that becomes progressively projectile. The infant otherwise appears well and will feed vigorously until late in the clinical course. The typical age at diagnosis is between 2 and 12 weeks of age. A history of identified feeding intolerance and formula change is common.

The definitive clinical finding on examination is a palpable, hypertrophied pylorus in the right upper quadrant to midepigastriac region, often described as a firm, mobile “olive” on examination. This is a pathognomonic finding, and in the correct clinical setting, no further diagnostic imaging studies are required. An experienced clinician should be able to palpate a hypertrophied pylorus in nearly all cases. A successful physical examination requires an empty stomach, a quiet infant, and patience; repeated examinations may be necessary. Inability to palpate the pyloric mass in a quiet or anesthetized infant should place the diagnosis of hypertrophic pyloric stenosis in question. Other physical findings include visible or palpable gastric peristaltic waves, which also can be seen with any cause of gastric or duodenal obstruction.

Late findings with advanced symptoms include dehydration and a hypochloremic, hypokalemic metabolic alkalosis from gastric fluid losses. Profound metabolic alkalosis is less common in current practice but occasionally can be encountered in an extremely dehydrated infant with a long-standing history of emesis. The intravascular volume depletion and chloride-

FIGURE 107.37. Infantile hypertrophic pyloric stenosis demonstrated by barium upper gastrointestinal series showing pyloric channel narrowing (N) and elongation with antral shouldering or cushioning (arrows).

responsive alkalosis must be corrected prior to operative repair. The serum chloride should be restored to at least 90 to 95 mEq/L, and the measured CO_2 should be less than 30 mEq/L prior to induction of general anesthesia.

Diagnosis. If the examination is equivocal, either an upper gastrointestinal contrast series or a pyloric ultrasound examination can be performed. Both examinations are highly accurate and have sensitivity and specificity exceeding 95% in experienced hands. A typical contrast study demonstrating a narrowed, elongated pyloric channel is shown in Figure 107.37. Contrast studies have the advantage of evaluating other causes of symptomatic emesis, including gastroesophageal reflux disease, malrotation, and antroduodenal webs. The disadvantage of this approach is the presence of contrast in a poorly emptying stomach. Ultrasound examination of the pylorus is a preferred diagnostic test in most pediatric institutions. Ultrasound criteria for hypertrophic pyloric stenosis include a pyloric muscle thickness of 4 mm or greater, and a pyloric channel length of 15 mm or greater. In general, the diagnosis of hypertrophic pyloric stenosis is being made at an earlier age compared with several decades ago.

Treatment. Hypertrophic pyloric stenosis is a progressive situation that subsequently resolves over several weeks to months. Nonoperative treatment during this period requires either long-term parenteral or enteral nutrition and is not practical from a risk or cost standpoint. The Ramstedt pyloromyotomy has achieved universal acceptance because it offers definitive, rapid cure in virtually all infants, and morbidity rates have been negligible (Fig. 107.38). The operation is performed once the infant is rehydrated and the serum electrolytes are corrected. Typically, the pylorus is delivered through a transverse right upper quadrant incision. A single longitudinal incision is made in the hypertrophied pyloric muscle. The hypertrophied circular pyloric muscle must be meticulously divided from the stomach to the junction of the proximal duodenum. An adequate pyloromyotomy is achieved when the submucosa bulges into the myotomy site and both

FIGURE 107.38. Ramstedt pyloromyotomy for infantile hypertrophic pyloric stenosis. The cross-sectional view shows herniation of the submucosa into the myotomy site, indicative of an adequate myotomy.

edges of the divided pyloric muscle are freely mobile. Laparoscopic pyloromyotomy has been demonstrated to be efficacious and safe with similar operative times and outcome to the open repair; laparoscopic pyloromyotomy has become a standard approach at most children's hospitals.^{121,122}

Postoperative feeding typically is started within 6 to 8 hours after recovery from anesthesia. Most infants are tolerant of enteral feeding and can be discharged home safely within 24 hours of operation. The surgical treatment of pyloric stenosis is straightforward, and the recovery is typically uncomplicated. A population-based study reviewing 1,777 infants with pyloric stenosis demonstrated a shorter length of stay and a lower overall complication rate in infants operated on by specialty-trained pediatric surgeons compared to general surgeons.¹²³ Mortality following pyloromyotomy is distinctly unusual in the absence of concomitant medical problems. Complications are rare and usually represent either wound infection, technical failures related to an inadequate pyloromyotomy, or inadvertent entry into the duodenum or stomach. Rarely, infants with inadequate pyloromyotomy may require reexploration and a second myotomy on the posterior pyloric wall. Inadvertent duodenotomy or gastrotomy must be recognized and repaired.

Intussusception

- 6 Anatomy and Physiology.** *Intussusception* is defined as the invagination or telescoping of a proximal segment of intestine into an adjacent distal segment and is the most common cause of intestinal obstruction in infants and children age 3 months to 3 years (Fig. 107.39). The invaginated proximal bowel is referred to as the *intussusceptum*, and the recipient distal bowel is called the *intussusciptiens*. This process most commonly originates in the small intestine either at or near the

FIGURE 107.39. Ileocolic intussusception with the intussusceptum and intussusciptiens indicated.

ileocecal valve, with the terminal ileum passing into the cecum and colon (ileocolic intussusception). In the pediatric population, the vast majority (95%) of cases are considered idiopathic because of a lack of an identifiable anatomic lesion causing the intussusception. Older children are more likely to have a pathologic lead point causing the intussusception. In similar fashion, infants and children with repeated episodes of intussusception have a greater probability of a pathologic lead point. Table 107.6 describes several factors that have been associated with the development of intussusception.

Many cases of idiopathic intussusception in infants are probably caused by the normally prominent intramural lymph nodes (Peyer patches) in the terminal ileum acting as functional lead points. The anatomic consequence of intussusception is obstruction of the distal bowel. As bowel edema and inflammation progress, mesenteric vascular insufficiency from compression and congestion may occur. Incarceration, strangulation, and intestinal perforation ultimately may result if this condition remains unrecognized or untreated.

OTHER

Cystic fibrosis

^aThese factors are more likely to be associated with small bowel-to-small bowel intussusception than with ileocolic intussusception.

Clinical Presentation. Intussusception is estimated to occur with an incidence rate of 1 to 4 cases per 1,000 children. There is a slight (3:2) male predominance; in a large retrospective series of children with intussusception, 79% were younger than 12 months, and seasonal variation in incidence was not observed.¹²⁴ An association between the development of intussusception and the administration of a previously available, tetravalent rhesus-based rotavirus vaccine (RotaShield, Wyeth Laboratories, Inc., Marietta, PA) was reported.¹²⁵ The currently available rotavirus vaccine does not appear to be associated with intussusception.¹²⁶

Otherwise healthy infants who develop intussusception may have a characteristic clinical triad of abdominal pain, vomiting, and bloody stool. The typical infant develops an acute onset of severe, colicky abdominal pain. Intermittent episodes of irritability and crying may be associated with drawing the legs up to the abdomen. Between bouts of colic, the infant is often lethargic or sleepy. During periods of relative exhaustion, the abdominal examination may not be impressive; however, on careful physical examination, a palpable mass in the right abdomen may be appreciated in 80% to 90% of cases. Emesis is common and is often the presenting complaint. As intestinal obstruction progresses, intractable vomiting with abdominal distention and intravascular volume depletion may occur. Guaiac-positive stool is present in 90% to 95% of infants as a result of the ischemic mucosal injury to the intussusceptum. The passage of bloody stool mixed with mucus, classically described as *currant-jelly stool*, may be observed.

Diagnosis. Plain radiographs of the abdomen are generally nonspecific and may show a paucity of gas in the right lower

FIGURE 107.40. Contrast enema demonstrating classic ileocolic intussusception with the intussusceptum visible in the ascending colon (arrows).

quadrant with a mass effect in the ascending colon. Late findings demonstrate mechanical small bowel obstruction with proximal distention, air-fluid levels, and a decrease or absence of gas distally. Diagnostic enema techniques using either air or contrast approach 100% accuracy with typical ileocolic intussusception (Fig. 107.40). An approach using hydrostatic or pneumatic enema allows therapeutic reduction of intussusception as well. Ultrasound examination typically reveals a mass resembling a bull's-eye or target sign, corresponding to the intussusceptum within the intussusciens. The target sign of intussusception also may be demonstrated by CT scan imaging. Neither of these latter modalities allows for potential therapeutic reduction, and both may be more useful in diagnosing suspected cases of proximal jejunoileal or enteroenteral intussusception.

Treatment. Any infant with suspected intussusception in the absence of peritonitis should undergo diagnostic hydrostatic or pneumatic enema. A high index of clinical suspicion and liberal application of this approach should be maintained. The incidence of normal contrast enema examinations in this setting may exceed 75% in most pediatric centers, and this is justified by the considerable risk inherent in a missed diagnosis. An experienced pediatric radiologist and surgical evaluation are essential. Intravenous access and resuscitation should occur before attempts are made at diagnostic or therapeutic enemas.

Successful hydrostatic or pneumatic reduction of ileocolic intussusception is achieved in 60% to 80% of infants in most pediatric centers in the United States. Some centers prefer pneumatic enema using air as a contrast agent, and this technique appears comparable to the hydrostatic approach in both diagnosis and therapeutic reduction of intussusception. The ability to reduce intussusception using these techniques is time dependent and diminishes substantially after the duration of symptoms exceeds 24 hours. In this setting, a contrast enema

is still diagnostic and potentially therapeutic if carefully performed.¹²⁷ With most experienced pediatric radiologists, the risk of perforation or reduction of a strangulated intussusception is low.

The technique of retrograde reduction of intussusception is straightforward. Contrast or air is introduced into the rectum by a balloon catheter, with the height of the hydrostatic column 1 m or less. Most centers use three attempts at reduction, with each attempt no longer than 3 minutes in duration. As long as progress is being made, however, attempts can be repeated until reduction is achieved. Successful reduction of ileocolic intussusception is demonstrated by observing retrograde flow of contrast or air into the terminal ileum. Inability to demonstrate retrograde flow into the ileum suggests incomplete reduction requiring surgical exploration.

Operative Management. Infants presenting with peritonitis and small bowel obstruction with a clinical diagnosis of intussusception should undergo immediate resuscitation and exploration without attempts at retrograde enema. Surgical exploration also is required after incomplete retrograde enema reduction of intussusception or in the relatively infrequent situation of bowel perforation during diagnostic or therapeutic enema. The operative strategy is dictated by the findings. Spontaneous reduction of the intussusception is reported to occur in up to 20% to 30% of infants following induction of general anesthesia. In this situation, exploration confirming the reduction and examining the bowel for a pathologic lead point is sufficient. With persistent intussusception and viable bowel, the bowel is manually reduced, generally pushing the intussusceptum out of the distal bowel. If manual reduction cannot be performed or the intussusceptum is strangulated, then segmental resection with primary anastomosis is performed. Attempts at reducing intussusception with clearly necrotic bowel should be avoided. Diverting enterostomy as a result of peritoneal contamination usually is not required. Appendectomy is routinely performed in all infants undergoing operative exploration for intussusception. As with many aspects of pediatric surgery, a successful laparoscopic approach to the diagnosis and management of intussusception has been reported in approximately two thirds of selected patients.^{128–130}

Complications and Outcome. Retrograde techniques are successful at reducing idiopathic ileocolic intussusception in 60% to 80% of cases. Following successful enema reduction, the infant is given intravenous fluids and usually observed for 24 hours. Tolerance of oral feeding is predictably rapid. Recovery from operative reduction or bowel resection is generally no different than from other similar gastrointestinal procedures. Most infants enjoy a complete recovery with minimal or no morbidity. Recurrent intussusception after either nonoperative or operative reduction occurs in about 5% of infants and usually can be treated with repeat enema. Mortality from intussusception is rare and is almost always the result of systemic sepsis and shock from unrecognized, strangulated intestine.

Meckel Diverticulum and Related Disorders

Embryology and Anatomy. The most frequently encountered congenital anomaly of the gastrointestinal tract is the Meckel diverticulum, representing one of several malformations resulting from persistence of the yolk stalk (synonymous with *vitelline duct* and *omphalomesenteric duct*) and its components. The embryonic yolk stalk connects the yolk sac and the developing midgut (Fig. 107.41). Between weeks 5 and 7 of gestation, the yolk sac involutes and the stalk fuses with the umbilical cord. Developmental failure or arrest of yolk sac involution creates a spectrum of clinical malformations as outlined in Figure 107.42, with Meckel diverticula constituting greater than 95% of these anomalies. The Meckel diverticu-

FIGURE 107.41. Normal embryonic relations of the yolk sac, yolk stalk, and developing gut.

lum is a true diverticulum of variable size derived from the intestinal remnant of the yolk stalk. Typically, it is found on the antimesenteric border of the terminal ileum approximately 40 to 50 cm from the ileocecal valve in adults. The blood supply is derived from persistent vitelline vessels supplied from the SMA. About 25% of the diverticula have a fibrous or vascular attachment to the anterior abdominal wall at the umbilicus (Fig. 107.42C). Heterotopic gastric mucosa or pancreatic tissue is found in about half of the diverticula examined at autopsy. In about 75% of patients with symptomatic diverticula, gastric mucosa is present. When symptoms occur, bleeding or perforation is generally the result of peptic ulceration of the adjacent ileal mucosa and not from the diverticulum itself.

Clinical Presentation. Symptomatic yolk stalk anomalies are usually diagnosed by history and clinical examination. Umbilical drainage from a persistent fistula or sinus tract may be noted in a newborn following separation of the umbilical cord. Intestinal prolapse or passage of stool from the umbilicus signifies a patent omphalomesenteric duct. Small bowel obstruction in an otherwise healthy infant without a history of laparotomy may be a result of volvulus around an omphalomesenteric band or intussusception from a Meckel diverticulum acting as a lead point.

The incidence rate of Meckel diverticula in the general population is about 2%, with a 2:1 male-to-female predominance. The risk of developing symptoms from the diverticulum decreases with age, and the vast majority of subjects remain asymptomatic. About half of the persons who do become symptomatic are younger than 2 years of age. Table 107.7 outlines several of the more common clinical presentations of symptomatic Meckel diverticulum.

Hemorrhage. Gastrointestinal bleeding related to Meckel diverticulum generally results from peptic ulceration of the adjacent ileal mucosa. Clinically, it manifests as painless, episodic hemorrhage that is typically bright red to maroon; melena is not characteristically seen. Bleeding from a Meckel diverticulum is generally not hemodynamically significant or exsanguinating, but it can be persistent enough to require transfusion. The diagnostic test of choice is the ^{99m}Tc-pertechnetate radioisotope scan (Meckel scan) because of the high affinity of the isotope for gastric mucosa and the high probability of gastric mucosa within a symptomatic Meckel diverticulum. Diagnostic accuracy is reported to be as high as 90% for

FIGURE 107.42. Common variants of yolk stalk malformations. **A** and **B**: Meckel diverticulum can manifest with inflammation (diverticulitis) or hemorrhage from acid-induced ulceration. **C** and **D**: Meckel diverticulum in association with abnormal band attached to the abdominal wall predisposing to volvulus and intestinal obstruction. **E**: Patent omphalomesenteric duct. **F**: Omphalomesenteric sinus and cyst formation.

Meckel-related bleeding. Contrast studies and endoscopy have a limited role when the problem is hemorrhage from a Meckel diverticulum.

Obstruction. Intestinal obstruction associated with omphalomesenteric duct anomalies usually results from either intussusception or volvulus around an abnormal attachment between the bowel and the abdominal wall. In about 5% to 10% of persons with symptomatic Meckel diverticula, intussusception is the initial symptom. In patients with Meckel diverticula whose initial symptom is small bowel obstruction, about half have intussusception and the remainder have volvulus, internal hernias, or other mechanical causes. Intussusception secondary to a Meckel diverticulum has a decreased likelihood for successful enema reduction. Small bowel obstruction from volvulus around an omphalomesenteric band requires operative exploration and treatment.

Diverticulitis. About one third of patients with symptomatic Meckel diverticulum have acute diverticulitis. Similar to appendicitis, intraluminal obstruction at the base of a Meckel diverticulum can lead to distal inflammation, gangrene, and subsequent perforation. Peptic ulceration also can lead to local inflammation and perforation with the development of peritonitis. The signs and symptoms of Meckel diverticulitis are virtually indistinguishable from appendicitis, and exploration is both diagnostic and therapeutic.

Umbilical Anomalies. About 10% of patients with yolk stalk or persistent omphalomesenteric duct anomalies have umbilical problems. The usual clinical presentation is persistent drainage or intestinal mucosa found at the umbilicus. The diagnosis can be confirmed by contrast sonogram of the umbilical orifice or tract. Occasionally, ultrasound examination may be useful to demonstrate omphalomesenteric cysts. Ultimately, surgical exploration may be required for both diagnosis and treatment.

Meckel Diverticulum as an Incidental Finding. The management of an incidentally discovered Meckel diverticulum during abdominal exploration for other reasons is controversial. The risk of resecting an asymptomatic diverticulum must be weighed against the reasons for the operative exploration, patient age, and the potential for future symptoms from the diverticulum. Infants younger than 2 years are at greater probability of becoming symptomatic from a Meckel diverticula. Resection is clearly indicated with demonstration of heterotopic gastric mucosa in the diverticulum to prevent peptic ulceration. This finding may occasionally be determined by direct palpation because the gastric mucosa is thicker than ileal mucosa. Abnormal omphalomesenteric bands to the abdominal wall also should be excised. If clinical judgment suggests that the diverticulum is at risk for luminal obstruction, resection is warranted.

Treatment. Infants and children with symptomatic umbilical abnormalities from yolk stalk remnants are usually well, and umbilical exploration with possible laparotomy can be undertaken electively. The yolk stalk remnant is excised, and, if present, the communication with the ileum is closed primarily with minimal morbidity and mortality. Operative exploration is required for patients with symptomatic Meckel diverticula. Typically, exploration can be accomplished through a variety of incisions. The treatment of choice is resection through either antimesenteric wedge excision or segmental bowel resection with primary closure or anastomosis. Laparoscopic diagnosis and management of a Meckel diverticulum has also been described.¹³¹ In the absence of associated medical problems, excellent functional outcome is expected with minimal morbidity and essentially no mortality unless intestinal necrosis has occurred.

Other	Uncommon

Foreign Bodies

Ingestion of foreign bodies by infants and children is common. Toddlers in the age range of 9 months to 2 years are at particular risk given newly acquired mobility and the tendency for oral exploration. The type of foreign body and the location in the gastrointestinal tract on discovery dictate overall management.

Esophagus. Typical foreign bodies found in the esophagus include coins and small toys. In normal children, these objects become impacted at predictably narrow portions of the esophagus, including the cricopharyngeus, the esophagus at the level of the left mainstem bronchus, and the gastroesophageal junction. Previous areas of esophageal repair or injury predispose to points of obstruction. In particular, infants and children with repaired esophageal atresia, gastroesophageal reflux, or caustic esophageal injury are at risk for impaction at these sites.

Esophageal foreign bodies produce clinical symptoms of drooling, feeding intolerance (particularly to solids), dysphagia, and pain. Unrecognized foreign bodies with unusual configuration or sharp points and edges may cause esophageal perforation and mediastinitis. The diagnosis is straightforward on plain radiographs if the object is metallic or radiopaque. If a radiolucent object is suspected, an upper gastrointestinal contrast study is usually required to confirm the diagnosis. Lateral plain films of the neck or chest may be useful to differentiate between small foreign bodies in the esophagus or trachea.

Foreign bodies impacted in the esophagus cause partial esophageal obstruction and can cause complications including aspiration, erosion, perforation, and late stricture formation. Therefore, all esophageal foreign bodies should be removed. Extraction of foreign objects can be accomplished by using balloon catheter retrieval under fluoroscopic guidance or direct visualization using endoscopy. Performed within 24 hours of ingestion, balloon catheter retrieval of esophageal foreign bodies is relatively straightforward. This technique is limited to smooth radiopaque objects such as coins to minimize the risk of esophageal perforation. The most significant risk with balloon catheter retrieval is potential aspiration from an unprotected airway, and this must be anticipated as the foreign body traverses the pharynx. Alternatively, for esophageal coin impaction of less than 24 hours' duration in children without a history of esophageal surgery or injury, esophageal bougienage with clearance of the coin into the stomach has been successful.¹³²

Retrieval of esophageal foreign bodies under direct endoscopic vision requires general anesthesia. Either flexible or rigid endoscopy systems are widely available and used with individual and institutional preferences. Esophageal perforation, the major risk, occurs in fewer than 5% of cases in most reported series. Long-standing esophageal foreign bodies may erode into the aorta and cause life-threatening hemorrhage from aorto-esophageal fistula.¹³³

Distal Gastrointestinal Tract. More than 95% of foreign bodies that pass beyond the gastroesophageal junction proceed uneventfully through the gastrointestinal tract. The transit time for an asymptomatic foreign body is highly variable and can take hours to weeks. Progress of an asymptomatic radiopaque foreign body can be followed by abdominal plain films, but this is rarely useful from a clinical standpoint unless it is a battery. The stool may also be screened to confirm passage of a known foreign body.

Operative exploration or endoscopic retrieval of distal gastrointestinal foreign bodies is generally reserved for clinical symptoms related to either obstruction or intestinal injury heralded by abdominal pain, vomiting, fever, or peritonitis. Additionally, persistence of an asymptomatic foreign body in the stomach for several weeks is a relative indication for upper endoscopic retrieval, particularly with foreign bodies with irregular shape, configuration, or sharpness. This is a clinical

judgment that is best reserved for an experienced pediatric surgeon because remarkably complex and improbable objects may pass uneventfully through the gastrointestinal tract. For asymptomatic foreign bodies lodged distal to the stomach, a relative indication for operative removal is a fixed, persistent location in the intestine for longer than 1 week.

Ingested batteries, in particular alkaline disc batteries, are a potentially serious hazard to children and require a more aggressive approach. Disruption of the battery casing and spillage of the contents have been reported to cause intestinal injury and perforation, presumably because of leakage of potassium or sodium hydroxide. Esophageal impaction of a battery warrants prompt removal when recognized because the risk of acquired esophageal injury, perforation, and development of traumatic tracheoesophageal fistula is present.¹³⁴ In the distal bowel, cathartics may be helpful to expedite passage of the battery. Operative removal may be necessary if the battery fails to progress distally over a few days or if symptoms related to the battery occur. Notably, the vast majority of batteries pass through the gastrointestinal tract uneventfully. Ingestion of multiple magnets can cause problems with small bowel obstruction or enteroenteric fistula formation.

Gastrointestinal Hemorrhage

The subject of gastrointestinal hemorrhage and general principles of management are discussed elsewhere in this book. The following section reviews some of the important and age-dependent clinical causes and unique issues of gastrointestinal bleeding in the pediatric population. These causes are age dependent and are summarized in Tables 107.8 and 107.9.

Diagnostic workup of an infant or child with gastrointestinal hemorrhage requires coordinated participation between pediatricians, surgeons, gastroenterologists, and radiologists. Several general principles governing the diagnostic approach to gastrointestinal bleeding in infants and children follow:

- A clear diagnosis can be made in most situations; given the current technology available to assist with diagnosis, an aggressive approach is warranted. Diagnostic procedures such as flexible fiberoptic endoscopy, radioisotope imaging, and angiography are widely available, safe, and applicable to any age group, including the newborn. Despite these measures, in approximately 16% of cases, the cause of guaiac-positive stools in a neonate or infant remains unknown,¹³⁵ and the bleeding is self-limited.
- The primary diagnostic investigation of choice for upper gastrointestinal bleeding is esophagogastroduodenoscopy. This procedure is optimally performed within the first 24 hours after cessation of active hemorrhage and usually requires general anesthesia. Imaging studies for active upper gastrointestinal hemorrhage are limited in their ability to aid with diagnosis.
- Infants and children presenting with minor lower gastrointestinal bleeding are best evaluated by a careful perineal and digital rectal examination followed by anoscopy.
- Massive lower gastrointestinal hemorrhage in an infant or child outside the newborn period is most likely the result of a bleeding Meckel diverticulum.
- If a definitive source for lower gastrointestinal hemorrhage is not found on colonoscopy, evaluation for an upper gastrointestinal source, including upper endoscopy and diagnostic laparoscopy, is warranted.
- Pain is an uncommon symptom with pediatric gastrointestinal hemorrhage and implies a more complex problem such as volvulus, ischemic bowel, or inflammatory bowel disease. Painful gastrointestinal hemorrhage in a pediatric patient requires urgent evaluation and prompt diagnostic workup.
- In contrast to that in adults, gastrointestinal bleeding in children is rarely a symptom or sign of gastrointestinal neoplasm.

TABLE 107.8

ETIOLOGY

CAUSES OF UPPER GASTROINTESTINAL HEMORRHAGE^a

PATIENT AGE GROUP	COMMON CAUSES	LESS COMMON CAUSES
Neonatal (0 to 30 days)	Gastritis Esophagitis Ingested maternal blood Peptic ulcer	Iatrogenic trauma Primary coagulopathy Vascular malformation (hemangioma, telangiectasia, arteriovenous malformation) Nasal or pharyngeal bleeding Miscellaneous (leiomyoma, gastric polyp, duplication)
Infant (30 days to 1 year)	Gastritis Esophagitis Peptic ulcer	Same as neonate, with addition of: Drugs (steroids, nonsteroidal anti-inflammatory drugs) Foreign body, caustic ingestion Esophageal varices
Child (1 to 12 years)	Esophageal varices Esophagitis Peptic ulcer	Same as infant, with addition of: Acquired thrombocytopenia (chemotherapy)
Older child (12 years to adult)	Esophageal varices Esophagitis Peptic ulcer	Same as for child

^aOrder in appearance approximates clinical frequency.

Neonates (0 to 30 Days of Age). The most common cause of gastrointestinal hemorrhage in a neonate is gastritis. Endoscopic evaluation of newborns with symptomatic upper gastrointestinal hemorrhage demonstrates gastritis or esophagitis in 50% to 75% of cases. About 10% to 15% have swallowed maternal blood during birth, and 10% of newborns are found to have an underlying coagulopathy. Anatomic lesions requiring operative control are distinctly unusual in this age group. Significant and sometimes massive upper gastrointestinal hemorrhage may occur in a neonate without a definable anatomic lesion despite endoscopic evaluation. This finding is usually the result of gastritis, and treatment is directed at blood and volume replacement and correction of any underlying coagulopathy.

Significant conditions responsible for lower gastrointestinal bleeding in the newborn include NEC, malrotation with volvulus, enterocolitis, or bowel obstruction secondary to an incarcerated inguinal hernia. These clinical entities present with characteristic histories, findings on clinical examination, and surgical treatment guidelines previously discussed. Anorectal fissure is also common and easy to diagnose in neonates, and bleeding is typically self-limited.

Infants (30 Days to 1 Year). Infants with upper gastrointestinal bleeding deserve comprehensive evaluation, including endoscopy, to identify potential lesions requiring operative intervention. The most common causes of lower gastrointestinal hemorrhage in this age group include infectious diarrhea, intussusception, food allergy, and bleeding Meckel diverticulum. Most of these lesions have distinct symptoms, signs, and diagnostic findings to facilitate diagnosis. Infectious diarrhea is usually accompanied by fever, feeding intolerance, possibly emesis, and abdominal pain. Fecal leukocytes may be present

on stool examination, and enteric pathogens or their toxins can be identified by stool culture.

Children (1 to 12 Years). An important surgical cause of upper gastrointestinal bleeding in this age group includes esophageal variceal bleeding from portal hypertension. Children with biliary atresia or extrahepatic portal venous obstruction account for most cases of variceal bleeding in this age group. In the acute setting, endoscopic sclerotherapy or banding is used as a temporizing measure for hemorrhage control; some investigators advocate maintenance sclerotherapy. Ultimately, for these children, orthotopic liver transplantation may offer definitive surgical treatment. The use of operative portosystemic shunts for acute variceal hemorrhage is not widely used in pediatric surgical practice in the United States.

Conditions causing lower gastrointestinal bleeding in this age group include juvenile polyps. These are benign, hamartomatous polyps and represent the single most common cause of lower gastrointestinal bleeding in children. About 20% to 30% of the polyps are palpable on digital rectal examination. A history of painless, bright red blood per rectum during a bowel movement is typical. The bleeding results from mucosal irritation, involution, and sloughing of a pedunculated polyp and is usually not associated with hemodynamically significant hemorrhage. Tissue may be passed or the pedunculated polyp may prolapse out the anus. A hypochromic, microcytic anemia may be present. Diagnostic workup generally involves a contrast enema to identify the polyp and evaluate the colon for synchronous lesions. Colonoscopy may require general anesthesia in this age group, and endoscopic snare polypectomy is the treatment of choice for appropriate-sized polyps. Infrequently, transanal excision or open resection of larger polyps is required. In the case of multiple juvenile polyps not

TABLE 107.9

ETIOLOGY

CAUSES OF LOWER GASTROINTESTINAL HEMORRHAGE^a

PATIENT AGE GROUP	COMMON CAUSES	LESS COMMON CAUSES
Neonatal (0 to 30 days)	Benign anorectal lesions (fissure) Upper gastrointestinal hemorrhage Milk allergy Necrotizing enterocolitis Midgut volvulus	Iatrogenic trauma Primary coagulopathy Vascular malformations Enterocolitis (Hirschsprung disease, other) Miscellaneous (duplication, lymphoma, lymphangiectasia)
Infant (30 days to 1 year)	Incarcerated inguinal hernia Benign anorectal lesions Idiopathic intussusception Meckel diverticulum Infectious diarrhea Upper gastrointestinal hemorrhage Milk allergy	Same as neonate, with addition of: Acquired thrombocytopenia Ingestion of colored foodstuff (pseudohematochezia)
Child (1 to 12 years)	Benign anorectal lesions Juvenile polyps Intussusception Meckel diverticulum Infectious diarrhea Upper gastrointestinal hemorrhage	Same as infant, with addition of: Juvenile polyposis coli/familial polyposis coli Hemolytic uremic syndrome Henoch-Schönlein purpura Systemic vasculitis (dermatomyositis, lupus) Acquired thrombocytopenia (as above plus idiopathic thrombocytopenic purpura)
Older child (12 years to adult)	Juvenile polyps Benign anorectal lesions Inflammatory bowel disease Upper gastrointestinal hemorrhage	Same as child, except: Henoch-Schönlein purpura and hemolytic uremic syndrome less likely Meckel diverticulum

^aOrder in appearance approximates clinical frequency.

amenable to endoscopic polypectomy, management may be expectant based on the benign natural history characterized by involution during adolescence. Histologic confirmation is necessary to differentiate these lesions from adenomatous polyps seen in familial polyposis syndromes or Gardner syndrome.

Older Children and Adolescents (Older than 12 Years).

Causes of both upper and lower gastrointestinal hemorrhage in this age group include most etiologic conditions found in adults. It is important that inflammatory bowel disease is significant in this age group.

Intestinal Duplication

The embryologic origin of enteric duplication formation remains controversial, but duplication likely represents abnormal development of either a diverticulum or adjacent portion of the developing gut. In some cases, duplication cysts of the upper gastrointestinal tract may be associated with thoracic spinal cord or vertebral defects; this association appears to reflect abnormal sequestration and integration of developing primitive notochord elements in addition to duplication. The resulting lesions are described as either *cystic* or *tubular* based on their gross appearance (Fig. 107.43). All types of gastrointestinal-derived epithelia are found, but the clinically relevant finding is ectopic gastric mucosa. Duplications are commonly found

along the mesenteric border of the native bowel. The muscular wall is typically well developed and intimately attached to the functional bowel. Additionally, the blood supply is also shared with the functional intestine, an important surgical consideration.

Cystic Duplications. Cystic duplications may be found throughout the gastrointestinal tract. They are frequently located in the esophagus and the hindgut, particularly the rectum. Direct communication between a duplication cyst and the functional gut lumen is unusual. Typically, asymptomatic duplications are discovered as incidental mass lesions during diagnostic imaging studies, particularly when the location is the thoracic cavity or the rectum. Duplications also may present as symptomatic lesions from ectopic gastric mucosa leading to ulceration and bleeding. Other potential presenting symptoms of enteric duplication include obstruction, intussusception, perforation or traumatic rupture, torsion, infection, and occasional malignant degeneration. Useful examinations to define the extent of the lesion include ultrasound, CT scanning, MRI studies, and contrast studies. The identification of enteric duplication on routine prenatal ultrasound examination has been reported.

The treatment for all cystic duplications is operative. Even in asymptomatic infants and children, uncertainty regarding the nature of the mass and the potential for subsequent problems dictates surgical exploration. Esophageal and rectal duplication cysts are generally amenable to simple excision. In

FIGURE 107.43. Enteric duplication. A: Cystic duplication of the terminal ileum. B: Tubular duplication of the terminal ileum and colon.

contrast, duplication cysts of the small intestine usually require segmental resection and primary anastomosis, given the intimate attachment and shared blood supply with the native bowel. For large cystic duplications involving longer segments of native bowel, individualized treatment strategies are required. One option is cyst marsupialization with resection of the duplication cyst wall with preservation of the common blood supply and wall between the cyst and native bowel. This technique is combined with submucosal dissection and stripping of the remaining epithelium from the cyst wall. Another approach is internal drainage of the cyst into the adjacent native intestine, for example, creation of a cystoduodenostomy for duodenal duplication not amenable to local resection and anastomosis; this would be distinctly unusual.

Tubular Duplications. Tubular duplications may be found anywhere along the length of the gastrointestinal tract. They

are less frequent than cystic duplications and have a tendency to involve the ileum and the colon. It is believed that tubular duplication generally reflects abnormal, disordered recanalization of the gastrointestinal tract. Similar to cystic duplications, tubular lesions share a common wall and blood supply with the native bowel. Communication between the tubular duplication and native bowel lumen is common. Tubular duplications may be extensive and can involve the entire length of terminal ileum and colon. Malformations of the entire colon and rectum are associated with genitourinary anomalies, particularly duplications of the external genitalia or bladder.

Tubular duplications manifest clinically in similar fashion to cystic lesions. Symptomatic lesions most commonly present with gastrointestinal bleeding or obstruction. Treatment is operative, and an individualized strategy is required that is based on the location and nature of the duplication. Resection with primary anastomosis may require removal of an unacceptable length of normal bowel. Marsupialization with submucosal stripping of the duplication epithelium may be particularly helpful if ectopic gastric mucosa is suspected or found. Obstruction from a long, blind-ending parallel duplication that communicates with the functional gut lumen can be treated effectively with a reentry procedure such as a distal enteroenterostomy. This approach avoids a potentially complex resection of a significant length of bowel.

The outcomes of surgical management of enteric duplications are generally excellent in the absence of other associated anomalies or medical problems. Mortality attributable to the duplication itself is unusual. Postoperative morbidity is generally dependent on the nature and location of the duplication.

Mesenteric and Omental Cysts

Mesenteric and omental cysts are rare lesions thought to result from the sequestration of lymphatic tissue during development. Mesenteric cysts are twice as common as omental cysts. Both are characterized by thin, often incomplete walls lined with endothelial cells absent of surrounding smooth muscle. They may be filled with either serous lymphatic fluid or chyle and may be unilocular or multilocular. These cysts may become extraordinarily large before producing symptoms.

Most infants and children with mesenteric or omental cysts are diagnosed prior to adolescence. Asymptomatic children are usually diagnosed incidentally during studies for other reasons. Symptomatic children present with abdominal pain, and, on examination, a soft, mobile abdominal mass is characteristic. Bleeding, rupture, obstruction, torsion, or cyst infection may be observed. Most of these lesions can be diagnosed by ultrasound or CT scan imaging. Ascites, duplication cysts, pancreatic pseudocysts, and large ovarian cysts may have a similar appearance on diagnostic imaging. Peripheral calcification and evidence of recent hemorrhage may be seen in mesenteric or omental cysts (Fig. 107.44).

The treatment for these lesions is simple excision. Total excision of mesenteric or omental cysts is generally preferable over partial excision with marsupialization. Limited resection with primary anastomosis may be required for a mesenteric cyst located adjacent to the intestinal wall, particularly if there is concern that the cyst actually may be an enteric duplication. Morbidity and mortality are generally limited to concurrent problems associated with the intestine. In particular, volvulus of a mesenteric cyst may cause vascular compromise and infarction of the adjacent intestine.

Primary Peritonitis

Bacterial peritonitis without a specific, identifiable cause is referred to as *primary peritonitis*. Spontaneous bacterial peritonitis in children with ascites or nephrosis is generally

FIGURE 107.44. Computed tomography scan image from a child after abdominal trauma. Hemorrhage into large omental cyst is apparent (arrows).

included in this group. Hematogenous seeding of ascitic fluid is probably responsible for the development of spontaneous bacterial peritonitis. The infecting bacterial organisms were classically gram-positive with various staphylococcal, streptococcal, and other species accounting for most cases. In a series of infants and children with primary peritonitis, more than two thirds of the cases were caused by gram-negative organisms such as *Escherichia coli*.¹³⁶ This trend may reflect the use of antibiotic prophylaxis directed against gram-positive organisms.

The other etiologic mechanism for the development of primary peritonitis is believed to involve retrograde inoculation of the peritoneal cavity via the genitourinary tract. This etiology is characteristic of prepubertal girls 5 to 10 years of age, accounting for as many as half of the cases of primary peritonitis. The initial signs and symptoms in these children are virtually identical to children with perforated appendicitis: fever, emesis, abdominal pain, and tenderness on examination. Leukocytosis is characteristic, and an ileus is observed on plain abdominal films. On exploration, these children have inflammatory peritonitis without an identifiable enteric cause. Gram-negative enteric organisms are commonly cultured from the peritoneal fluid.

Infants and children with peritonitis in association with an indwelling peritoneal dialysis catheter or ventriculoperitoneal shunt may be treated successfully with intravenous broad-spectrum antibiotics. The catheter or shunt should be removed or exteriorized promptly if peritonitis does not resolve within 24 to 48 hours.¹³⁷ In association with ascites or nephrosis, diagnostic paracentesis should be performed and the peritoneal fluid examined by Gram stain and culture. If there is any diagnostic uncertainty, laparoscopic or open operative exploration may be required to exclude intestinal perforation as a cause of peritonitis. If the appendix is normal, peritoneal cultures should be obtained and a thorough, complete abdominal exploration for other causes should be performed. Appendectomy is generally performed when the diagnosis of primary peritonitis is established by a right lower-quadrant incision. Other than perforated appendicitis, distinct causes of intestinal perforation or peritonitis in this age group include perforated Meckel diverticulum, duodenal ulcer, and acute pancreatitis. About half of the peritoneal fluid cultures are positive for a single organism. Treatment with specific antibiotics is continued until the patient is afebrile with a normal white blood cell count and normal clinical examination. Following operative exploration in primary peritonitis, the morbidity is no different than that for appendectomy, and the recovery is generally uneventful.

α_1 -Antitrypsin deficiency
Idiopathic

Ascites

The common causes of neonatal and childhood ascites are listed in Tables 107.10 and 107.11. The clinical presentation is that of abdominal distention with bulging flanks and demonstrable fluid on palpation and percussion. Ultrasound or CT scan imaging may be useful to confirm the clinical diagnosis. Paracentesis and routine examination of the fluid for Gram stain, cell count, cytology, protein, chemistries, and culture should be performed. Chylous ascites is characterized by a white milky appearance, high lymphocyte count, and high triglyceride content. Bile-stained fluid in the absence of demonstrable bowel perforation is characteristic of biliary ascites. High fluid amylase content is seen in pancreatic ascites, and a low protein count (<3 g/dL) is consistent with serous ascites. Elevated urea nitrogen or creatinine in the fluid may suggest urinary ascites, particularly in a male patient. Cytology should be performed to exclude peritoneal ascites secondary to malignancy, particularly in pubertal and adolescent females.

If the initial fluid does not provide a diagnosis in an otherwise normal-appearing child, a comprehensive diagnostic imaging evaluation is warranted. An echocardiogram should be performed and either ultrasound or CT scan imaging performed to evaluate the genitourinary system, the hepatobiliary system, and the pancreas. A voiding cystourethrogram may also be indicated.

Treatment of neonatal or childhood ascites depends on the establishment of a specific diagnosis. In the absence of anatomic lesion or injury, spontaneous resolution of chylous ascites occurs in 50% to 75% of cases with the temporary cessation of enteral feeding and administration of parenteral nutrition. Persistence of chylous ascites for longer than 4 to 6 weeks is an indication for operative attempts to ligate the cisterna chyli. Neonatal biliary ascites may result from spontaneous bile duct perforation, in which case a diagnosis of CF must be considered. Transient bile duct obstruction typically leads to perforation at the junction of the cystic duct with the common duct. Simple external drainage is the treatment of choice, and complex hepatobiliary tract reconstruction in this setting is unnecessary and potentially hazardous. Urinary ascites in a male patient requires

a workup that includes a voiding cystourethrogram to exclude posterior urethral valves. Urinary ascites resolves with treatment of obstructive uropathy. Pancreatic ascites is typically self-limited, and treatment by drainage procedures is generally not required or limited for relief of persistent symptoms.

Massive neonatal ascites may cause hypoventilation secondary to impairment of diaphragmatic excursion, and therapeutic paracentesis may be required. Childhood ascites generally responds to adequate treatment of the underlying problem and occasionally requires medical therapy. Placement of a peritoneovenous shunt in children for intractable ascites is rare.

Rectal Prolapse

Spontaneous rectal prolapse is relatively common in toddlers and children up to 5 years of age. A peak incidence occurs at or

near the time of toilet training. There is an association between straining during bowel movement and rectal prolapse; it may be more commonly observed in children with CF, myelodysplasias with sacral neuropathy, congenital anorectal malformations, Hirschsprung disease, and colorectal polyps. However, most children presenting with rectal prolapse are normal.

A history of protrusion of mucosa or full-thickness rectum with or without bleeding is usually described. Other lesions of childhood that have a similar appearance are prolapse of an intussusceptum or passage of a polyp through the anus. The rectal examination is diagnostic. If the protruding intestine is an intussusceptum, a finger can be placed adjacent to it within the rectum; this maneuver is not possible with rectal prolapse.

Nonoperative management using manual reduction is successful in most infants and children. Sedation may be required in some instances. Therapeutic interventions include stool softeners and parental instruction on manual reduction. Spontaneous resolution over a few weeks is typical. For persistent rectal prolapse in children, operative intervention is generally governed by doing the least invasive procedure possible. Unlike in adults, complex operations involving bowel resection and pelvic suspension are generally unnecessary in children with rectal prolapse. The most useful and commonly used procedure is rectal submucosal injection using a sclerosant (Fig. 107.45). With the patient under general anesthesia, injection with 5% sodium morrhuate or cow's milk¹³⁸ has been performed successfully on an outpatient basis. About 90% of children can be treated successfully with a single four-quadrant sclerosant technique, but on occasion further sclerosis is necessary. Submucosal dissection or cauterization is also successful but may have a higher incidence of postoperative bleeding or stricture formation and usually requires a short period of hospitalization. The major objective in treating childhood rectal prolapse is to create a local extraperitoneal inflammatory process in the perirectal space. Morbidity is low and the long-term outcome is excellent.

PEDIATRIC LIVER

Tumors of the Liver

Primary hepatic tumors are rare in children, and at least 60% to 70% are malignant.^{139,140} Table 107.12 reviews the incidence rates and types of hepatic tumors presenting during infancy and childhood. Pediatric hepatic tumors often manifest as asymptomatic abdominal masses discovered by parents or pediatricians. Symptoms related to the tumor, such as pain, hemorrhage, hypertension, and precocious puberty, are less frequent. Initial diagnostic imaging studies include plain abdominal radiographs and ultrasound to assist in early determination as to whether the mass is cystic or solid and whether calcifications are present. CT scan imaging and MRI remain definitive in the ability to discern anatomic characteristics of the mass and its relationship to adjacent structures. Most children require operative exploration for either definitive excision or for incisional biopsy in lesions deemed unresectable.

Benign Tumors. Of all primary liver tumors of childhood, 30% are benign. The most common benign tumors are hemangiomas, hemangioendotheliomas, mesenchymal hamartomas, cysts, focal nodular hyperplasia, and hepatic adenoma. In most large series, hemangiomas constitute about 50% of the benign hepatic tumors observed.¹⁴¹

Vascular Tumors. Infantile hepatic hemangiomas represent a clinically diverse spectrum of vascular endothelial anomalies. They are characterized by a phase of proliferative growth over the first year of life, with subsequent involution over several years. The International Society for the Study of Vascular Anomalies classifies vascular tumors into two categories based

FIGURE 107.45. Four-quadrant injection of sclerosant into the rectal submucosa for the treatment of childhood rectal prolapse.

on the presence or absence of GLUT-1, an erythrocyte-type glucose transporter protein expressed in the endothelium of the placenta and hemangiomas.¹⁴² Therefore, hemangiomas are GLUT-1 positive, and other, more heterogeneous vascular anomalies such as vascular malformations are GLUT-1 negative. Most asymptomatic infantile hepatic hemangiomas are detected as incidental findings on diagnostic imaging studies performed for unrelated reasons. A smaller proportion will create symptoms of enlarging abdominal mass, progressive hepatic failure, high-output cardiac failure due to shunting, thrombocytopenia, or hypothyroidism from excess production of type III iodothyronine deiodinase.¹⁴³

Most benign vascular lesions of the pediatric liver do not require operative management. Operative intervention is generally reserved for bleeding secondary to traumatic rupture symptoms not controllable with medical management. Treatment strategies remain highly individualized based on whether the

lesions are focal, multifocal, or diffuse.¹⁴⁴ In the face of multifocal or diffuse disease associated with congestive heart failure and thrombocytopenia secondary to sequestration, medical treatment with corticosteroid therapy may be useful. More invasive procedures such as irradiation, selective hepatic arterial ligation, angiographic embolization, or hepatic transplantation remain useful in selected patients with uncontrollable symptoms. Chemotherapeutic agents, including recombinant alpha-interferon, low-dose vincristine, and cyclophosphamide have been used for life-threatening vascular lesions. Hepatic resection is generally reserved for mass lesions of unknown diagnosis, ruptured vascular lesions with signs of active hemorrhage, or for symptomatic, locally resectable lesions.

Hemangioendotheliomas are important vascular anomalies encountered in infants. The lesions vary in size from 1 cm to several cm in diameter and may be multiple (Fig. 107.46).

FIGURE 107.46. Selective visceral angiogram demonstrating large hepatic vascular malformation in a neonate with congestive heart failure. This finding is consistent with a bilobar hemangioendothelioma.

Symptomatic neonates may present with an abdominal mass, hepatomegaly, and congestive heart failure. These infants may also experience spontaneous rupture and hemoperitoneum, with tachycardia, tachypnea, and hypovolemic shock. On examination, the infant may have other cutaneous hemangiomas visible on the skin. Affected infants may develop thrombocytopenia secondary to platelet sequestration in the vascular malformation (*Kasabach-Merritt syndrome*). CT scan imaging or MRI is diagnostic. Treatment is directed at controlling symptoms using medical management principles as discussed previously; however, hemangioendotheliomas tend to be more problematic than hemangiomas because of the tendency to occur during infancy and the more extensive, symptomatic nature of the lesions.

Mesenchymal Hamartomas. Approximately one third of benign hepatic tumors in children are mesenchymal hamartomas. A mesenchymal hamartoma is often quite large and typically presents within the first year of life as an asymptomatic, solitary abdominal mass. CT scan imaging or MRI studies are usually diagnostic and show a solid mass that may have cystic components within the liver parenchyma. Definitive diagnosis may require open tissue biopsy, and the therapy of choice is complete excision, although spontaneous involution has been described. Simple enucleation may be adequate because these tumors tend to be well circumscribed. On occasion, formal hepatic resection may be required.¹⁴⁵ Recurrence is low after adequate resection.

Focal Nodular Hyperplasia. This tumor occurs primarily in female children and in adults and may be associated with the use of oral contraceptives or focal hepatic injury. Focal nodular hyperplasia is usually a well-defined, solitary mass that has characteristic findings on CT scan imaging. Open or percutaneous biopsy may be required to differentiate the lesion from hepatic adenoma. This lesion results from a focal inflammatory response of normal hepatic parenchyma surrounded by areas of micronodular fibrosis and cirrhosis. Operative management is generally unnecessary unless there is a question of diagnosis or active hemorrhage from the lesion.

Hepatic Adenoma. Adenomas are rare in infants and children and constitute less than 5% of all benign hepatic lesions in the pediatric age group. There is an association between the use of oral contraceptives, exogenous anabolic steroid use, and glycogen storage disease type I (von Gierke disease). These tend to be large, solitary lesions located in the right hepatic lobe. The typical presentation is an asymptomatic abdominal mass, although symptoms are seen more commonly than with focal nodular hyperplasia. About 20% to 25% of patients with hepatic adenoma present with hemoperitoneum from tumor rupture. On histologic examination, these lesions are composed of normal hepatocytes without evidence of dysplasia. Operative therapy is usually directed at either making definitive diagnosis or treating hemorrhage. Enucleation or local resection is adequate, and recurrence rates are low.

Hepatic Cysts. Congenital cysts of the liver may be either solitary or multiple. These cysts are thought to result from failure of the intralobular or interlobular biliary ducts to fuse during development. They may be lined with cuboidal, columnar, or squamous epithelium.¹⁴⁶ The presence of multiple hepatic cysts is associated with polycystic kidney disease, and development of progressive hepatic and renal failures are potential problems with this disease. Most children with hepatic cysts are asymptomatic. Adjunctive diagnostic imaging, including ultrasound and CT scan imaging, may be useful.

Asymptomatic congenital hepatic cysts do not require surgical therapy. Operative therapy is reserved for symptomatic cysts. Resection or drainage by marsupialization or hepaticocystoenterostomy may be required. If patency to the biliary

tract is present on contrast injection study of the cyst, internal drainage is necessary.

The differential diagnosis includes hydatid disease of the liver, which is suggested by calcification and loculation of the cyst wall. Hydatid disease can be diagnosed using specific serologic tests, which is an important surgical consideration prior to exploration. Patients with echinococcal cysts should be treated with mebendazole and undergo cyst injection with hypertonic saline or other scolicidal agents into the parent cyst before surgical excision. Careful control of the cyst contents is required during echinococcal cyst excision or marsupialization.

Teratomas. Teratomas of the liver are exceedingly rare and have potential for harboring immature elements capable of transforming into malignancy. Surgical resection on discovery is recommended.

Malignant Tumors. Two thirds of childhood hepatic tumors are malignant, with hepatoblastoma constituting half of the malignancies, followed by hepatocellular carcinoma, malignant mesenchymal tumors, and sarcoma.¹³⁹ Malignant hepatic tumors are fortunately rare, and effective treatment requires a multidisciplinary approach that is best achieved in an experienced pediatric center.

Hepatoblastoma. Most hepatoblastomas are discovered in children younger than 2 years of age. There is a 2:1 male-to-female predominance. Hepatoblastomas usually are found as either an asymptomatic abdominal mass or symptoms of gastrointestinal obstruction from extrinsic compression by the mass. There is an association of hepatoblastoma in patients with Beckwith-Wiedemann syndrome and hemihypertrophy. On examination, a firm, palpable upper abdominal mass is notable. Obstructive jaundice is unusual. More than 90% of children with hepatoblastoma have elevated levels of alpha-fetoprotein, which is a useful serum tumor marker for postoperative surveillance. In a few instances, children have initial symptoms and signs of excess androgen secretion, including virilization and precocious puberty. Diagnostic imaging with CT scan imaging or MRI is essential to evaluate the extent of the tumor and evaluate for metastatic disease (Fig. 107.47).

Most children presenting with hepatoblastoma initially have unresectable disease. In the absence of metastatic disease, however, an aggressive surgical approach is used. Cure and long-term survival with hepatoblastoma requires complete surgical excision of the primary lesion. Therefore, localized, resectable tumors usually are excised by formal hepatic lobectomy or extended trisegmentectomy. Children with hepatoblastomas considered initially unresectable or with metastatic

FIGURE 107.47. Computed tomography scan of the abdomen demonstrating an infant with hepatoblastoma of the right hepatic lobe.

disease should undergo percutaneous or incisional biopsy to confirm the histologic diagnosis, followed by multiagent chemotherapy to reduce the size of the primary tumor and control metastases.^{147,148} Delayed resection is appropriate if enough functional, normal hepatic parenchyma remain after resection. More than half of the patients who initially have unresectable hepatoblastoma can be rendered disease-free with the combination of chemotherapy and subsequent surgery. Cure rates for hepatoblastoma range from 60% to 80% if histologically clear margins and no metastatic disease are present. All patients with hepatoblastoma, regardless of stage, receive chemotherapy after resection. Unfortunately, cure cannot be expected in children treated with chemotherapy and radiation therapy alone without complete surgical resection.

Hepatocellular Carcinoma. Hepatocellular carcinoma is significantly more common in adults but is occasionally seen in older children and adolescents. There is a male predilection (2:1), and except for the age at diagnosis, the clinical presentation is similar to that for hepatoblastoma. Children with hepatocellular carcinoma are more likely to have jaundice and abnormal liver enzymes. The high association of cirrhosis in adults (80%) is not seen in children with hepatocellular carcinoma; only 5% of children develop hepatocellular carcinoma in the background of cirrhosis. An increased risk of hepatocellular carcinoma is seen in children with Beckwith-Wiedemann syndrome, hemihypertrophy, von Gierke disease, hepatitis B, and Fanconi syndrome. Exposure to oral contraceptives, anabolic steroids, and some chemotherapeutic agents also has been associated with hepatocellular carcinoma. This malignancy carries a poor prognosis with an overall survival rate of 10% to 20% despite aggressive surgical resection and multiagent chemotherapy. A histologic variant, fibrolamellar hepatocellular carcinoma, carries a more favorable prognosis. As with hepatoblastoma, complete surgical resection with clear histologic margins is necessary for long-term survival and cure. In the absence of metastatic disease, unresectable hepatoblastoma or hepatocellular carcinoma in children has been successfully treated by orthotopic liver transplantation. A review of data from the United Network for Organ Sharing database demonstrates good long-term survival for both hepatoblastoma (66% 10-year survival) and hepatocellular carcinoma (58% 10-year survival) treated with liver transplantation.¹⁴⁹

Malignant Mesenchymal Tumors. These rare hepatic malignancies occur in children 5 to 10 years of age; initial signs are fever, pain, and an abdominal mass, which is usually quite large on diagnosis and may have both solid and cystic components. Multidisciplinary treatment, including complete surgical resection, multiagent chemotherapy, and radiation therapy is required for cure. In general, the prognosis of primary malignant mesenchymal tumors of the liver remains poor.

Sarcomas. Children may rarely have a primary sarcoma of the liver. Embryonal rhabdomyosarcoma of the biliary tract is distinctly unusual. It may manifest with obstructive jaundice attributable to both extrinsic and intrinsic biliary tract obstruction. Undifferentiated, embryonal sarcoma of the liver has also been described. Angiosarcoma developing in the liver may be associated with exposure to toxins such as arsenic. Aggressive surgical resection may be required, but long-term survival is uncommon. Despite radical surgery, chemotherapy, and radiation therapy, the prognosis and long-term survival of children with these malignancies remains poor, and data regarding effective drug regimens are limited.^{150,151}

Liver Resection

Operative principles and techniques for hepatic resection are discussed elsewhere in this book. Several unique issues in the safe performance of hepatic resection in children should be emphasized.¹⁵² Contemporary management of hepatic resection for tumors in children requires adequate preoperative assessment and the liberal use of intraoperative monitoring techniques. The circulating blood volume of an infant or child is small compared to that of an adult, and children are sensitive to compression of the inferior vena cava causing decreased venous return to the right heart. Blood must be available for transfusion, and adequate intravenous access is essential. Resection can be performed through either a subcostal or a right thoracoabdominal incision; in general, the ability to perform the operation safely should not be limited by the size of the incision. In children, the right and left hepatic veins are difficult to control near the inferior vena cava because of their short lengths, and intraparenchymal control from an anterior approach may be safer (Fig. 107.48). Resection may be performed using total hepatic vascular isolation by

FIGURE 107.48. A: The hepatic veins in infants and children may be extremely short, making extrahepatic control impossible or dangerous. B: Intrahepatic control of the hepatic veins via an anterior approach may be safer in infants and children.

controlling the hepatic and portal inflow, the suprahepatic inferior vena cava, and the suprarenal inferior vena cava caudal to the liver. When extrahepatic biliary duct reconstruction is required, T-tube drainage is not routinely performed given the small diameter of the ducts in most children.

Hepatic Infections

Hepatic infections are generally rare in the pediatric population, and their management is similar to that used in adults. An important issue is the development of hepatic abscess in an immunocompromised child, and in particular, the association of chronic granulomatous disease with pyogenic hepatic abscess formation.

Pyogenic Abscess. The most common cause of pyogenic liver abscess before the advent of antibiotic therapy was perforated appendicitis. Now the most common causative factor in the development of pyogenic hepatic abscess in children with chronic granulomatous disease and other causes of immunosuppression.¹⁵³ Chronic granulomatous disease is an inherited disorder characterized by a defect in oxidative burst-mediated bacterial killing by neutrophils. These children develop skin, soft tissue, and solid organ abscesses. A significant number of children with pyogenic liver abscesses have chronic granulomatous disease or other inherited/acquired immunodeficiency states. Liver abscesses are infrequently seen as a complication of umbilical vein catheterization, omphalitis, biliary tract disease, and hepatobiliary operations.

Patients with pyogenic liver abscess present with fever, jaundice, and leukocytosis. Hepatosplenomegaly and a tender liver may be found on physical examination. Diagnostic imaging with ultrasound, CT scan imaging, or MRI is useful. Common responsible organisms include staphylococcal species, streptococcal species, and *E. coli*. Gram-negative organisms and anaerobic bacteria are becoming increasingly prevalent. Treatment involves the use of broad-spectrum antibiotics. Large abscess cavities may require image-guided percutaneous drainage to expedite resolution of sepsis. Currently, few hepatic abscesses require open operative drainage. The outcome is dependent on the underlying disease process. Recovery from the abscess is predictably good following adequate antibiotic therapy and drainage when necessary.

Amebic Abscess. Amebic abscess of the liver is uncommon in the United States, but it is endemic to areas of Central and South America. It is caused by infection with the parasite *Entamoeba histolytica*. Children with amebic dysentery develop hepatic infection as the parasite travels through the portal circulation. Patients have a history of chronic illness, fever, and abdominal pain. Examination typically demonstrates a tender right upper quadrant. Infection can be confirmed by a serum antibody test, and amebic abscess can be demonstrated by ultrasound or CT scan. Spontaneous rupture of amebic abscess is reported in as many as 10% of patients in some series.¹⁵⁴ The treatment of choice is the antibiotic metronidazole. Surgical resection or drainage of amebic liver abscess is typically not required for resolution.

PEDIATRIC BILIARY TRACT

Common biliary tract problems including infectious, inflammatory, and gallstone-related problems are managed similarly in both children and adults, and the management principles are discussed elsewhere in this text. Two congenital problems of the biliary tract, namely, biliary atresia and congenital cystic disease of the biliary tract (choledochal cyst), are somewhat unique to infants and children in presentation and management and are reviewed in the following discussion.

Embryology

The fetal liver and biliary tract develop between weeks 4 and 10 of gestation, representing the fusion of an endodermal foregut diverticulum with a mesodermal component from the septum transversum. The hepatocytes are derived from cords of endodermal cells in the hepatic diverticulum and ultimately give rise to the hepatic sinusoidal endothelium. The proximal hepatic diverticulum gives rise to the extrahepatic biliary tract, including the gallbladder, cystic duct, and common bile duct. As the intrahepatic and extrahepatic ductal systems develop, they unite to form a connected, arborizing system of cords composed of primitive ductular epithelial cells. These epithelial cells assume tubular configuration with ductal patency established between weeks 6 and 12 of gestation. Bile flow from the hepatocytes and into the biliary duct system is apparent by the beginning of the second fetal trimester.

This embryologic sequence appears to take place normally in infants who develop biliary atresia. In fact, the term *biliary atresia* does not reflect embryologic atresia resulting from failure of recanalization of the biliary tree. Rather, biliary atresia is caused by an uncontrollable inflammatory process that produces progressive obliteration of the normally developed extrahepatic biliary tract.

Biliary Atresia

7 Anatomy. The overall incidence rate of biliary atresia is about 1 in 8,000 to 12,000 live births and is the most common cause of chronic cholestasis in infants and children as well as the most frequent indication for pediatric liver transplantation.¹⁵⁵ Extrahepatic biliary atresia must be differentiated from biliary hypoplasia. Biliary hypoplasia describes a diminutive but patent biliary system and can result from many underlying situations such as neonatal hepatitis and α_1 -antitrypsin deficiency. Biliary hypoplasia involves both intrahepatic and extrahepatic ductal systems.

Microscopic Anatomy. Biliary atresia is characterized by replacement of the extrahepatic biliary tract with dense, fibrous inflammatory tissue. In most cases, complete obliteration of the extrahepatic biliary tract, including the gallbladder, occurs. There appears to be gradual progression of the inflammatory process with advancing age. The common hepatic duct and common bile duct are almost uniformly obliterated by the inflammatory process. Few or absent patent ductal remnants and an absence of portal inflammation may be associated with a less favorable prognosis.¹⁵⁶ Intraoperative evaluation for duct patency by frozen section analysis has historically been used to help guide the extent of proximal resection at the porta hepatis; however, this is no longer in widespread use. The presence of bile ducts at the porta hepatis with diameter greater than 150 μm has been reported to be associated with postoperative bile flow in up to 90% to 95% of cases.¹⁵⁷

Histologic features of biliary atresia reflect hepatic parenchymal injury. Neocholangiogenesis, or biliary duct proliferation of disorganized and nonpatent ducts within the liver, is considered highly suggestive but not specific for biliary atresia. Other findings include bile pigment deposition throughout the liver. Characteristic early findings in biliary atresia include evidence for acute inflammation with neutrophil predominance in the periportal regions. Older infants and children typically have chronic inflammatory changes with considerable fibrosis. Periportal bridging fibrosis is commonly seen in intermediate stages of the disease. Ultimately, progressive biliary atresia leads to intractable cirrhosis. Nearly all patients with biliary atresia have histologic evidence of liver injury. The severity and extent of liver damage may be the most important predictor of long-term outcome and survival in biliary atresia.

Pathophysiology. Despite numerous investigations, the mechanism causing biliary atresia remains unknown. The current, widely accepted concept is that the normally developed biliary tract undergoes inflammatory sclerosis and subsequent obliteration. This process appears to occur during the first few weeks to months of life. Infants who develop biliary atresia are rarely jaundiced at birth, and biliary atresia is either rare or nonexistent in fetal autopsy studies. Clinical data are consistent with the fact that biliary atresia appears to be a progressive, dynamic inflammatory response that is acquired during the perinatal period and targets the extrahepatic biliary tract. Early establishment of biliary drainage via portoenterostomy within the first 2 to 4 months of age may be associated with reversal of liver injury and subsequent long-term survival. Conversely, infants operated on after 120 days of life typically have obliterated bile ducts. Neonatal biliary atresia shares some clinical and morphologic features of sclerosing cholangitis in adults. Data supporting an infectious etiologic agent, and in particular reoviruses, rotaviruses, and hepatitis C, have been reported and may play a role in some cases. Additionally, other noninfectious stimuli may trigger an inflammatory response directed at the neonatal extrahepatic bile duct.¹⁵⁸ The actual mechanism may reflect a stereotypical inflammatory response initiated by various different stimuli that is ultimately directed preferentially against the neonatal bile duct.

Clinical Presentation and Diagnosis. The cardinal sign of biliary atresia is progressive neonatal jaundice during the first few weeks of life. Dark urine and acholic stools are expected findings. Progressive hyperbilirubinemia produces clinical jaundice around 2 to 4 weeks of age. The physical examination is generally unremarkable except for jaundice and possibly mild hepatomegaly. Alagille syndrome, which presents with neonatal jaundice, can usually be distinguished from biliary atresia on physical examination. Children with Alagille syndrome have biliary hypoplasia and distinctly abnormal facies, growth retardation, vertebral defects, and pulmonic stenosis.

A characteristic laboratory finding is conjugated hyperbilirubinemia consistent with obstructive jaundice. A direct fraction of bilirubin greater than 50%, or greater than 2 mg/dL in an infant, requires prompt investigation. Mild elevation of hepatic transaminases is commonly seen. The alkaline phosphatase is significantly elevated, often in the range of 500 to 1,000 IU/L. There are no specific biochemical markers for biliary atresia, as these serum profiles can be seen in other causes of neonatal cholestasis. Late findings in biliary atresia include failure to thrive, feeding intolerance, stigmata of portal hypertension, and fat-soluble vitamin deficiency.

Table 107.13 is a partial list of the causes of neonatal cholestatic syndromes. Neonatal physiologic jaundice is commonly encountered. This condition is self-limited once the glucuronyl transferase system matures, allowing the hepatocytes to conjugate bilirubin efficiently. Because of the numerous causes of neonatal jaundice and the relative infrequency of biliary atresia, a delay in diagnosis is common. Given the age-sensitive nature of biliary atresia and the improved outcome in younger infants, the diagnostic workup should be expedient.

Radioisotope Scanning. Technetium 99m-iminodiacetic acid (^{99m}Tc-IDA) analogues are widely used for hepatobiliary imaging and provide the basis for a sensitive and specific test for biliary atresia. The sensitivity of this diagnostic examination for biliary atresia can be 100% with a specificity of 94%.¹⁵⁹ To improve sensitivity, infants are administered oral phenobarbital (5 mg/kg daily) to induce hepatic microsomal enzymes and increase hepatocyte processing of ^{99m}Tc-IDA. Both hepatic uptake of radionuclide and excretion into the gastrointestinal tract are evaluated over a timed interval. Infants with primary hepatocellular disorders characteristically have impaired hepatocyte uptake of radionuclide, whereas normal infants and

infants with biliary atresia have prompt uptake. Normal infants excrete the isotope rapidly into the gut through the biliary tract. In biliary atresia, there is no excretion into the gut because of the obliteration of the extrahepatic bile ducts (Fig. 107.49). The hepatobiliary scan is a rapid test that can be performed simultaneously with other diagnostic examinations, for example, ultrasound. This test reliably identifies infants with choledochal cyst as well.

Other Diagnostic Tests. Several other diagnostic tests are of interest in the workup of an infant with conjugated hyperbilirubinemia in whom obstructive jaundice is suspected. MRI cholangiography is emerging as a sensitive, specific examination for identification of extrahepatic anatomy. The important management principle is that prompt operative exploration, liver biopsy, and cholangiogram should be performed in any infant in whom biliary atresia is suspected. An aggressive approach is warranted in that unnecessary delay in definitive drainage may lead to a less favorable outcome.

FIGURE 107.49. A: Normal scan using p-isopropylacetanilidoiminodiacetic acid (PIPIDA) as the hepatobiliary scanning agent. At 45 minutes, isotope is clearly visible in the liver (L) and intestine (I). B: Scan after phenobarbital administration in infant with biliary atresia. Even after 8 hours, isotope is apparent only in the liver and urinary bladder (UB). C: Patient with cholestatic jaundice. At 65 minutes, isotope is visible in the liver (L) and intestine (I). Hepatocyte uptake is variable but usually decreased or normal, whereas excretion into the gut is predictably present with cholestatic jaundice or hepatocellular disease.

Ultrasound. A standard examination of the jaundiced infant is a comprehensive abdominal ultrasound, with particular attention given to the liver and biliary tract. The most common ultrasonographic finding in biliary atresia is a diminutive or absent gallbladder without associated intrahepatic duct dilatation. Biliary tract obstruction from a choledochal cyst also can be reliably identified by ultrasound. Other rare causes of extrahepatic biliary duct obstruction are associated with proximal duct dilatation.

Liver Biopsy. Because the histologic findings in biliary atresia are not specific, about 20% to 25% of infants who undergo percutaneous liver biopsy remain undiagnosed. Liver biopsy is often performed in conjunction with the workup of conjugated hyperbilirubinemia following hepatobiliary scanning and ultrasonography, but in the setting of biliary atresia, it has limited utility. The histologic examination of a percutaneous liver biopsy is probably most helpful in diagnosing nonoperative causes of neonatal jaundice, thus avoiding anesthesia and operative exploration.

Alpha₁-Antitrypsin Deficiency. Alpha₁-antitrypsin deficiency is perhaps the single most important medical condition that may be difficult or impossible to differentiate from biliary atresia. All jaundiced infants should have plasma alpha₁-antitrypsin levels determined before operative exploration for suspected biliary atresia. Infants with alpha₁-antitrypsin deficiency do not benefit from operative exploration or portoenterostomy.

Treatment. Infants with biliary atresia require surgical therapy as the initial management intervention. Medical therapy is directed to the postoperative management of the chronic liver disease. The use of sequential surgical treatment, using portoenterostomy in infancy and orthotopic liver transplantation for children with progressive hepatic failure, provides improvement in overall survival.^{160,161} Limited organ availability and a higher rate of perioperative complications limit primary liver transplantation for most infants with biliary atresia younger than 1 year. In the rare instance of unrecognized biliary atresia in an older child with established hepatic dysfunction, primary orthotopic liver transplantation may be a reasonable option.

Portoenterostomy. The recommended initial procedure for the treatment of biliary atresia is portoenterostomy. Before the development of portoenterostomy in Japan by Morio Kasai during the late 1950s, all infants with biliary atresia died of chronic liver disease and cirrhosis. Current management dictates that operative exploration and portoenterostomy be performed promptly. Early intervention by portoenterostomy to provide

biliary drainage has been proposed to arrest or reverse the parenchymal liver injury, but the point at which the liver injury becomes irreversible remains unknown. From a clinical standpoint, most long-term success with portoenterostomy alone appears to be achieved in infants younger than 2 to 3 months, whereas infants older than 3 to 4 months appear to have a less favorable prognosis. Portoenterostomy for this “late” group has been reported successful in approximately one third of infants, however, and should be considered a potential alternative in the absence of available liver transplant donors.¹⁶²

The initial approach to the infant with suspected biliary atresia is to perform an operative cholangiogram. If the diagnosis is confirmed, a portoenterostomy is constructed (Fig. 107.50). To maximize the potential for effective biliary drainage with portoenterostomy, several technical caveats are worthy of mention. An open liver biopsy is routinely performed to document the state of parenchymal injury. The cholangiogram is generally attempted through the gallbladder. In the 10% to 15% instances of a patent distal biliary tree, treatment still requires portoenterostomy. A nonpatent, fibrous cord rather than a normal common bile duct is found in the hepatoduodenal ligament. This cord is dissected free proximally to the level of the porta hepatis between the portal vein bifurcation. The fibrous remnant is sharply transected at this level to preserve any patent bile ducts. A short, 15- to 25-cm retrocolic, jejunal Roux-Y limb is constructed. There has been no clear advantage with longer or modified conduits with intussusception-type antireflux valves in the prevention of cholangitis.^{163,164}

Previously, some surgeons preferred to exteriorize the biliary conduit (Fig. 107.51). With an exteriorized biliary conduit, postoperative bile flow is directly visible. The diverting stoma must be closed, however, and there is potential to develop parastomal variceal hemorrhage from progressive portal hypertension. Additionally, fluid and electrolyte losses from the biliostomy can be significant, and there are no reported survival differences between patients with exteriorized and closed biliary conduits following portoenterostomy. Because many of these infants may ultimately require liver transplantation, there is a trend toward using a simple, closed biliary conduit with portoenterostomy. Therefore, the use of a stoma to divert the bile flow in the Roux limb has been largely abandoned.

Results and Complications. Following portoenterostomy, bile flow occurs in about 66% to 75% of all infants when operated on at less than 60 days of age; however, establishment of bile flow may take weeks to months. The probability of bile flow appears related to age at the time of operation.

Cholangitis is a constant concern and an important postoperative problem after portoenterostomy. The clinical signs

FIGURE 107.50. The essential features of the portoenterostomy for biliary atresia include appropriate mobilization (A) and transection (B) of the fibrous biliary tract remnant. C: Creation of a Roux-Y jejunal conduit with biliary enteric anastomosis completes the procedure.

include fever, leukocytosis, and decreased bile flow in the absence of other systemic illness. All patients are at risk for the development of postoperative cholangitis, but reported postoperative rates of cholangitis are 40% to 50%. Cholangitis following portoenterostomy is characterized by a systemic inflammatory response and may be associated with progressive liver injury. Treatment is generally intravenous fluid resuscitation and broad-spectrum antibiotics. Occasionally, steroids or other anti-inflammatory agents may be helpful, whereas reoperation or endoscopic revision of the portoenterostomy usually is not.¹⁶⁵ In an effort to determine the optimal treatment of infants with biliary atresia, a group of investigators have formed the Biliary Atresia Research Consortium (BARC).¹⁶⁶ The primary objectives of the consortium are to establish a clinical database and tissue repository. A retrospective BARC study of 104 children with biliary atresia treated in the United States demonstrated that at 2 years of age, 58 patients were alive with their native liver and 42 had undergone liver transplantation.¹⁶⁷ Data from the United Kingdom demonstrated improved measurable outcomes in children with biliary atresia treated with Kasai portoenterostomy by regionalization of care to three centers in the U.K. health care system.¹⁶⁸

Nearly all patients with biliary atresia have residual liver injury. Hepatic synthetic failure, portal hypertension with esophageal variceal bleeding, hypersplenism, and fat-soluble vitamin deficiencies can be problematic. Most institutions report 5-year survival rates between 30% and 50% for portoenterostomy alone. About 25% to 35% of patients undergoing a portoenterostomy survive more than 10 years without liver transplantation. The remaining two thirds of children with biliary atresia ultimately require liver transplantation for survival. Although the failure rate for portoenterostomy is high, the possibility of long-term success is notable. Additionally, the limited availability of infant donor organs and the technical limitations of liver transplantation in infants younger than 1 year of age make portoenterostomy an accepted initial treatment of biliary atresia in most centers.

Hepatic Transplantation. Hepatic transplantation is discussed in detail elsewhere in this text. For biliary atresia, transplantation offers a means of long-term survival in children with failed portoenterostomies. The current 5-year survival of children with biliary atresia who undergo liver transplantation ranges from 75% to 94.4%.^{169,170} Additionally, with the use

FIGURE 107.51. Several types of conduits have been used for biliary drainage following portoenterostomy. There are relatively few data to help in selecting from among them, and current trends emphasize simplicity. These are the three most commonly used conduits. The primary importance of this issue is that the reoperative surgeon must be familiar with the anatomic variations.

of reduced-size cadaveric donor livers as well as living-related donor livers, the mortality rate for infants on transplant waiting lists may be decreasing. Indications for liver transplantation in biliary atresia include progressive hepatic failure despite portoenterostomy, growth retardation, and complications of portal hypertension. It is important to consider the consequences of lifelong immunosuppression in these children, including the risks of infection and treatment-related malignancy.

Congenital Choledochal Cystic Disease of the Biliary Tract

Anatomy. The anatomic description and classification scheme for choledochal cystic disease initially proposed by Alonso-Lej et al.¹⁷¹ in 1959 and modified by Todani et al.¹⁷² are illustrated in Fig. 107.52. The most frequently encountered are type I cysts, accounting for approximately 85% to 90% of the lesions in most series. Type I cysts are characterized by fusiform dilatation of the entire common bile duct with only mild dilatation of the common hepatic duct; the intrahepatic ducts are normal. Variations are common, and biliary atresia is occasionally seen in association with choledochal cystic disease.

Type I cysts are generally quite large and often cause displacement of neighboring viscera. The fusiform dilatation usually begins at the origin of the common bile duct, generally sparing the common hepatic ducts. The distal common bile duct is diminutive and typically is distorted mechanically by the large cyst, leading to the common clinical presentation of obstructive jaundice. The junction of the distal common bile duct and the pancreatic duct is not within the normal intramural duodenum but rather is extrinsic and proximal to the duodenal wall and the sphincter of Oddi (Fig. 107.53). It remains unknown whether the configuration of a long, extramural common channel allows greater pancreatic secretion reflux into the common bile duct.

Microscopic examination of the choledochal cyst wall reveals that the normal biliary epithelium is absent or replaced by abnormal and occasionally dysplastic columnar epithelium. The cyst wall has normal smooth muscle with variable degrees of inflammation and fibrosis. The exception to this common histologic characteristic is the type III cyst, which is generally lined by normal duodenal mucosa. Choledochal cysts tend to have less inflammation in infancy and early childhood. In contrast, there is well-established inflammation involving the cyst and surrounding structures in the hepatoduodenal ligament in adolescents and adults.

Pathophysiology. The mechanism for the development of cystic lesions of the biliary tract is unclear. Choledochal cysts have been identified accurately by prenatal ultrasound, and it appears likely that these lesions represent abnormalities in the developing biliary tract. Several hypotheses for the development of choledochal cyst have been proposed. Whether the cystic dilatations result from abnormal recanalization of the primitive bile duct cords or from inflammation caused by reflux of pancreatic secretions into the common bile duct remains unknown. The pathophysiology of choledochal cyst is that of obstructive jaundice. The obstruction may be primarily the result of mechanical outflow obstruction of a diminutive distal common bile duct with a dilated choledochal cyst. Alternatively, a large inflammatory cyst can cause obstruction of the biliary tract and of neighboring viscera by extrinsic compression. When discovered during infancy, obstructive jaundice is usually the initial clinical finding. The liver injury is typically reversible, and progression to biliary cirrhosis is rare. The exception to this situation is type V disease, which is associated with a high incidence of hepatic fibrosis.

Other initial clinical situations include cholelithiasis and acute bacterial cholangitis secondary to diminished bile drainage. Children with type III cysts may have acute pancreatitis. Infrequently, extrinsic compression of the portal vein by a large choledochal cyst may produce symptoms and signs of portal hypertension. Abdominal pain and tenderness following minor injury may lead to an incidental diagnosis of choledochal cyst on imaging studies.

Carcinoma of the biliary tract occurs in about 3% to 5% of patients with choledochal cyst. The number of reported cases remains small in the literature, but the incidence for biliary tract neoplasm is about 1,000 times that of the normal

FIGURE 107.52. Classification of choledochal cyst.

population.¹⁷³ Patients with choledochal cyst are at increased risk for the development of biliary tract carcinoma in adolescence or early adulthood. The dysplastic cyst epithelium may be susceptible to malignant change from chronic inflammation. It is interesting that there appears to be an increased risk of malignancy to develop anywhere in the biliary tract, gallbladder, or pancreas, and not just in the choledochal cyst itself.¹⁷⁴ Therefore, current treatment emphasizes complete cyst excision of the cyst epithelium while providing adequate biliary drainage to prevent stasis and chronic inflammation. Infants and children treated for choledochal cyst should have long-term follow-up for complications and potential malignancy.

Clinical Presentation and Diagnosis. Choledochal cysts present most commonly in infancy and early childhood with symptoms of obstructive jaundice. In older children and adults, the classic clinical triad of episodic abdominal pain, a palpable right upper-quadrant mass, and jaundice occurs in fewer than 50% of patients. Adults occasionally present with hepatomegaly or evidence of portal hypertension. The diagnosis in infants and most children can be confirmed by ultrasound examination and ^{99m}Tc-IDA imaging studies (Figs. 107.54 and 107.55). In older children, both MRI cholangiography and endoscopic retrograde cholangiopancreatography (ERCP) are highly sensitive and specific in confirming diagnosis. These

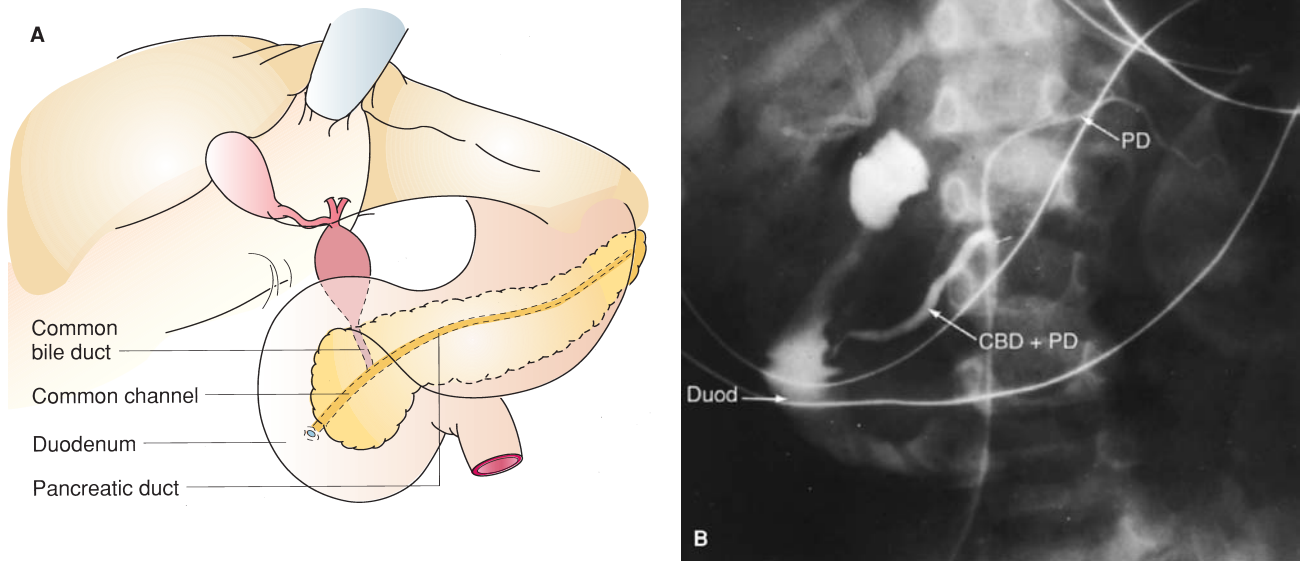

FIGURE 107.53. An anomalous, extramural junction between the distal common bile duct and the pancreatic duct is characteristic of type I choledochal cyst. **A:** Schematic depiction of this anatomy. **B:** Operative cholangiogram from a patient with a long extramural common channel. It has been suggested that the long common channel may allow reflux of pancreatic secretions into the common bile duct resulting in inflammation and proteinase-mediated injury to the common duct, possibly contributing to the development of the cyst itself. Duod, duodenum; CBD + PD, common bile duct and pancreatic duct; PD, pancreatic duct.

lesions also are diagnosed incidentally during radiologic imaging studies for other reasons. Partial duodenal obstruction may lead to an upper gastrointestinal series that shows extrinsic compression from a large type I cyst or an intraluminal filling defect from a type III cyst. CT imaging of the abdomen following blunt trauma may lead to the diagnosis of biliary tract dilatation. Liver biopsy is not specific in choledochal cyst and has little diagnostic role other than to document the extent of liver injury.

Treatment

Type I Cysts. Initial operative strategy for a type I choledochal cyst is exploration and cholangiography, usually through the gallbladder, but occasionally contrast injection must be made directly into the common bile duct. Cholecystectomy is rou-

tinely performed. Historically, internal drainage procedures without cyst excision were widely used. These procedures have been associated with a higher rate of failure because of stricture, stone formation, pancreatitis, and cholangitis. Additionally, there is the potential for development of biliary tract carcinoma in the retained cyst. Therefore, internal drainage procedures without cyst excision have been abandoned. Current consensus for the surgical management of type I choledochal cyst is performance of primary cyst excision with Roux-Y hepaticojejunostomy reconstruction (Fig. 107.56). Primary cyst excision is accomplished routinely in infants and children.¹⁷⁵ For adults with severe inflammation and fibrosis, dissection may present problems resulting from inflammation and adhesion of the cyst wall to the hepatoduodenal ligament. A safer approach in this situation may be intramural cyst dissection and removal of the cyst wall epithelium, leaving the

FIGURE 107.54. Typical ^{99m}Tc iminodiacetic acid (HIDA) scan from a child with a type I choledochal cyst. Images were made in 5 minutes (**A**), 30 minutes (**B**), and 3 hours (**C**) after isotope injection. The isotope is retained within the choledochal cyst more than 24 hours, and the pattern of hepatocyte uptake is normal.

FIGURE 107.55. Ultrasound image of a type I choledochal cyst (arrow; longitudinal image). The gallbladder (GB) is also shown.

posteromedial outer cyst wall adjacent to the portal vein and hepatic artery intact.

Other Types of Cysts. Type II cysts are excised completely and the choledochotomy closed primarily. Type III choledochoceles require a transduodenal approach with either marsupialization or excision of the cyst. Care must be taken to identify the ampulla, and a formal sphincteroplasty may be required to ensure adequate drainage from the biliary tract and the pancreas. Types IV and V intrahepatic cystic disease must be approached on an individualized basis. In general, unilobar or focal cystic disease can be either resected or drained with

Roux-Y jejunostomy reconstruction. In cases of bilobar intra-parenchymal disease, particularly in the setting of hepatic fibrosis, it may be difficult, if not impossible, to obtain complete, adequate drainage.

Complications and Outcome. The major complications associated with operative repair of choledochal cyst include cholangitis, stricture formation, choledocholithiasis, and development of biliary tract malignancy. A summary of the incidence of complications, mortality, and reoperation for the different procedures in 955 cases reported in the literature demonstrated a clear advantage for primary cyst excision in terms of morbidity and need for reoperation, and no significant increase in mortality occurred using this approach.¹⁷⁶ Subsequent to this analysis in 1975, internal drainage procedures without cyst excision have been essentially replaced by primary cyst excision with hepaticojejunostomy reconstruction. Currently, several series have reported excellent results with little or no mortality using total transmural excision of choledochal cysts.¹⁷⁷ Primary transmural excision with biliary tract reconstruction continues to be a safe and desirable operative approach for cystic lesions of the biliary tract.

PEDIATRIC PANCREAS

Disorders of the pancreas are uncommon in infants and children. Pancreatic disorders in children include congenital anatomic disorders, inflammatory pancreatitis, rare neoplastic lesions, and pancreatic endocrinopathies.¹⁷⁸ Several significant issues are relative to the pancreatic problems in the pediatric age group, and a brief overview is presented in the following discussion.

Embryology

The fetal pancreas arises from the paired dorsal and ventral foregut diverticular buds during the sixth week of gestation.

FIGURE 107.56. The preferred operative treatment of type I choledochal cyst consists of primary total transmural cyst excision with Roux-Y hepaticojejunostomy.

FIGURE 107.57. A: Normal pancreatic ductal anatomy. B: Pancreas divisum. There is no communication between the duct of Wirsung and the duct of Santorini. The duct of Wirsung is short or absent. Most of the pancreas is drained by the duct of Santorini through the accessory papilla. This anatomy is found in about 10% to 15% of normal individuals.

The dorsal pancreatic anlage gives rise to the body and tail of the pancreas as well as the main pancreatic duct. The ventral pancreatic anlage migrates 180 degrees to fuse with the dorsal gland, forming the uncinate process and the distal portion of the duct of Wirsung (Fig. 107.57). The independent ductal systems of the developing pancreatic anlage fuse. The dorsal (Santorini) duct opens directly into the duodenum, and this anatomy is persistent in 10% to 15% of normal subjects. The ventral (Wirsung) duct opens into the duodenum by fusion with the common bile duct. Normally, the dorsal duct fuses with the ventral duct just to the right of the mesenteric vessels. Failure of the dorsal and ventral ducts to fuse normally leads to two separate pancreatic ducts, a condition known as *pancreatic divisum*. Occasionally, the ventral duct regresses and the entire pancreatic gland is drained by the accessory duct of Santorini.

Primitive duct cells of the pancreas give rise to both the acinar cells and the islet cells of the normal pancreas. Primary islet cells become apparent at week 8 of gestation within the interlobular tissue, with acini becoming visible shortly thereafter. The primary islet cells regress after the fifth month of gestation and are usually nonexistent by term. Secondary islet cells arise from centroacinar proliferation during the third month of gestation. These intralobular cells migrate out of the acini in which they were formed and develop into islets that remain connected to the duct by a thin cellular stalk (the tubule of Bensley).

Exocrine pancreatic anomalies generally arise from defective development during embryogenesis. The most common of these conditions is annular pancreas. The circumferential distribution of pancreatic tissue around the duodenum is thought to result from interrupted migration of the ventral pancreatic anlage. Less common defects include pancreatic ductal abnormalities, pancreatic duplications, heterotopic pancreatic tissue, and congenital agenesis of portions of the pancreas.

Acute Pancreatitis

Acute pancreatitis is often overlooked as a cause of abdominal pain in children; however, it is the most common disorder of the pancreas in both infants and children. Adult pancreatitis is often

caused by either alcohol ingestion or gallstones. In contrast, 50% to 80% of cases in children, particularly adolescents, are posttraumatic or idiopathic in origin. An important clinical condition seen with moderate frequency is acute pancreatitis in the setting of immunosuppression, in particular, high-dose corticosteroids. Steroid-induced acute pancreatitis typically accounts for the third most common cause of pancreatitis in most children's hospitals. Other causes of acute pancreatitis include gallstones, CF, hyperlipidemia, juvenile diabetes mellitus, mumps, coxsackievirus infection, infectious mononucleosis, collagen vascular diseases, and anatomic lesions such as choledochal cyst. Medications significantly associated with acute pancreatitis include oral contraceptives, thiazide diuretics, tetracyclines, azathioprine, and L-asparaginase. Valproic acid, an anticonvulsant useful in some children with seizure disorders, is associated with a particularly virulent form of acute necrotizing pancreatitis that may be life threatening.

A child with acute pancreatitis presents with a history of midepigastri abdominal pain, anorexia, and emesis. On examination, the child usually has a tender abdomen with distention. Fever and leukocytosis are common. Serum amylase and lipase levels are elevated, although significant pancreatitis can occur despite a normal amylase level. Conversely, the lipase may be mildly elevated in the absence of clinical symptoms or signs of acute pancreatitis. Ultrasonography and CT imaging of the abdomen are probably the most commonly used adjunctive diagnostic tests. CT imaging is particularly useful in demonstrating edema of the gland as well as evaluating for peripancreatic fluid collections. Although usually deferred during the acute phase of pancreatitis, ERCP or MRI cholangiography may be useful to evaluate the hepatobiliary tract anatomy once the inflammatory process has resolved.

Treatment principles for childhood acute pancreatitis are not different from strategies used in adults. The vast majority of children have simple edematous pancreatitis. Hemorrhagic and necrotizing pancreatitis are distinctly unusual in this age group but can be seen in immunosuppressed patients. Therefore, initial therapy is designed to be supportive and nonoperative in approach. Endotracheal intubation and mechanical ventilation may be required. Intravenous fluid resuscitation, pancreatic rest by nasogastric tube decompression, analgesia,

and TPN are provided. No clinical efficacy data are available to support the widespread use of anticholinergics or somatostatin analogues for acute pancreatitis in children. Operative intervention is reserved for complications of pancreatitis such as hemorrhage, infected pancreatic necrosis, or pancreatic pseudocyst.

Recurrent pancreatitis in a child usually is associated with an anatomic abnormality or specific physiologic problem. Following recovery from the acute inflammatory event, an aggressive diagnostic workup, including consideration of ERCP or MRCP to define ductal anatomy, should be performed. In particular, the presence of pancreas divisum with stenosis of the accessory papilla should be considered. Children with pancreatitis in the setting of cholelithiasis should undergo laparoscopic cholecystectomy after resolution of the pancreatitis.

Pancreas Divisum

Pancreas divisum occurs with failure of normal fusion between the dorsal and ventral pancreatic ducts. About 10% to 15% of normal persons have two separate pancreatic ducts, and up to 10% of asymptomatic persons undergoing ERCP have two complete ductal systems. The anatomic variant of pancreas divisum is not necessarily pathologic, but if the orifice of the accessory papilla is stenotic or obstructed, pancreatitis can occur.¹⁷⁹ Approximately 25% of affected individuals are thought to be at risk for developing pancreatitis. Because pancreas divisum is characterized by a dominant dorsal duct system dependent on secretion through the accessory papilla, stenosis of the accessory (lesser) papilla is probably necessary to produce pancreatic symptoms. Most of the experience with surgical treatment of pancreas divisum is reported in adults. Successful surgical management of children presenting with recurrent pancreatitis secondary to accessory papilla stenosis with pancreas divisum also has been reported.¹⁸⁰

To diagnose pancreas divisum, ERCP is required. Endoscopic visualization of the major and accessory papillae is essential. Radiographic findings with pancreas divisum demonstrate a short or absent duct of Wirsung that does not communicate with the duct of Santorini (Fig. 107.57). Definitive diagnosis of pancreas divisum is made by demonstrating two separate, parallel ductal systems.

Few pediatric patients with pancreatitis and pancreas divisum requiring operation have been reported. Most of these children were female patients who had a history of recurrent pancreatitis. The primary operative goal is to provide adequate drainage of the duct of Santorini by performing a sphincterotomy of the accessory duct. An open dorsal duct sphincterotomy appears to be more durable than endoscopic sphincterotomy. Some surgeons advocate sphincterotomy of the main papilla as well, but dorsal duct sphincterotomy alone appears effective in preventing acute pancreatitis associated with pancreas divisum. The reported surgical outcome in the limited number of children treated for pancreatitis associated with pancreas divisum is favorable.

Pancreatic Cysts

Pancreatic pseudocysts are uncommon in the pediatric age group and are usually the result of blunt traumatic abdominal injury or acute pancreatitis. Children typically present with abdominal pain, nausea, emesis, and weight loss. There may be a palpable midepigastria mass on examination. Diagnosis usually is made with ultrasound or CT imaging of the abdomen. The serum amylase and lipase are usually elevated.

In children, many small asymptomatic pseudocysts regress spontaneously with resolution of the pancreatic inflammation. Larger or symptomatic pseudocysts may require drainage. Symptoms and potential complications of untreated pseudo-

cysts include hemorrhage, infection, perforation, gastrointestinal or biliary tract obstruction, or, rarely, development of pancreaticoenteric fistula. The decision to use either external or internal drainage procedures for a pseudocyst depends on the status of the pancreatic duct. In many centers, definitive external drainage of a large or symptomatic pseudocyst is performed with acceptable morbidity and mortality rates by an ultrasound- or CT-guided percutaneous approach.¹⁸¹ Pseudocyst recurrence or persistent external drainage without resolution suggests significant pancreatic duct injury or complete ductal transection. Determination of whether a major pancreatic ductal injury is associated with a pseudocyst may be made by either percutaneous contrast injection of the pseudocyst or ERCP.¹⁸² Pseudocysts associated with pancreatic duct injury may not resolve with percutaneous external drainage or endoscopic pancreatic duct stenting, so internal drainage procedures such as cystgastrostomy or cystojejunostomy with or without distal pancreatectomy may be required.¹⁸³

Epithelial cysts of the pancreas are rare in children. Congenital cysts are lined by epithelium and acinar tissue and are seen most commonly in the body and tail of the pancreas. They may be associated with other syndromes such as von Hippel-Lindau disease, which is characterized by hereditary cerebellar cysts, retinal hemangioma, and pancreatic cysts. Congenital pancreatic cysts are typically asymptomatic unless they are large enough to cause compression or obstruction of the stomach or colon. In the absence of trauma, spontaneous rupture of a pancreatic epithelial cyst is rare. Treatment is cyst excision or internal drainage into the stomach or jejunum.

Other rare cystic lesions of the pancreas in children include retention cysts. These cysts result from chronic ductal obstruction. They are characteristically lined by epithelium unless inflammatory obliteration has occurred. Enteric duplication cysts of the stomach or duodenum can also be associated intimately with the pancreas and communicate with the pancreatic duct. Treatment of both retention cysts and enteric duplication cysts either within or associated with the pancreas includes excision, occasionally internal drainage, and, if necessary, distal pancreatectomy. Not all pancreatic cysts in children can be uniformly considered benign. Suspicious lesions should be investigated thoroughly and biopsy performed. Cystadenoma, cystadenocarcinoma, and rhabdomyosarcoma associated with a pancreatic cyst have been reported. These neoplasms are treated by anatomic pancreatic resection following histologic confirmation on biopsy.

Pancreatic Neoplasms

Childhood malignant neoplasms of the pancreas are uncommon. Typically, pancreatic malignancy in childhood is found on discovery of an asymptomatic abdominal mass. Infrequently, the lesion may be found incidentally or during a diagnostic imaging workup for abdominal trauma. Jaundice may occur with a lesion in the pancreatic head causing common bile duct obstruction. The most frequently encountered lesions include islet cell carcinoma and adenocarcinoma. The treatment of choice for localized malignant neoplasms of the pancreas is surgical resection.¹⁸⁴ Pancreaticoduodenectomy in children can successfully control some malignancies of the pancreatic head. To promote adequate nutrient absorption and growth, children undergoing pancreaticoduodenectomy should be considered for oral pancreatic enzyme replacement and fat-soluble vitamin supplementation.¹⁸⁵

Two pancreatic neoplasms seen in childhood and adolescence deserve further discussion. The *papillary cystic neoplasm* of the pancreas occurs predominantly in younger female children, is typically slow growing with low malignant potential, and is highly curable with surgical resection.¹⁸⁶ This tumor is thought to be a neoplasm of the ductuloacinar primordial cells of the pancreas. The other lesion is the *pancreatoblastoma*, also

referred to as *juvenile adenocarcinoma of the pancreas*. Pancreatoblastoma is somewhat more common in boys than girls and typically has slow growth with low malignant potential as well. Histologic examination demonstrates undifferentiated ductular and acinar areas with nodules of squamous epithelium, suggesting that these tumors arise from primordial pancreatic cells. Both papillary cystic neoplasm and pancreatoblastoma have more favorable prognoses than adenocarcinoma following surgical resection.

Endocrine Lesions of the Pancreas

Zollinger-Ellison Syndrome. Childhood tumors of the endocrine pancreas are exceedingly rare. The diagnosis and management of these tumors do not differ greatly from those of the adult population. The most common of these lesions include gastrinoma and insulinoma. The functional endocrine tumors of the pancreas are characterized by secreted peptide products such as glucagon, vasoactive intestinal peptide, somatostatin, and pancreatic polypeptide.

Similar to adults, children with Zollinger-Ellison syndrome clinically present with symptoms related to gastric hypersecretion. Peptic ulcer disease with or without gastrointestinal hemorrhage, abdominal pain, and diarrhea are common presenting symptoms. The diagnosis is confirmed by finding elevated serum gastrin levels. The basal acid output typically is elevated as well. A paradoxical increase in serum gastrin levels is found following intravenous administration of secretin (secretin stimulation test).

Contemporary management of Zollinger-Ellison syndrome in children relies on control of gastric acid hypersecretion with the oral administration of a proton-pump inhibitor. Diagnostic imaging studies, including helical CT scanning and MRI, are useful in localization of a primary gastrinoma and evaluating for metastatic disease before exploration. Definitive treatment relies on complete excision of the primary gastrinoma, which typically is found in the right of the superior mesenteric vessels in the head of the pancreas or the duodenum. The growth and progression of gastrinoma appear to be less aggressive in children than in adults; however, total gastrectomy occasionally is required in a child to control intractable symptoms related to persistent hypergastrinemia or metastatic disease.¹⁸⁷

About 25% of gastrinomas occur in the setting of MEN syndrome, reviewed elsewhere in this book. At least 90% of patients with MEN type I have hyperparathyroidism secondary to hyperplasia. Additionally, 30% to 80% of patients have pancreatic islet cell tumors, and 15% to 50% have pituitary tumors.

Hypoglycemia. There are diverse metabolic causes for hypoglycemia in infancy and childhood. These include endocrinopathies such as panhypopituitarism, hypothyroidism, adrenal insufficiency, and congenital adrenal hyperplasia (adrenogenital syndrome). Several inborn errors of metabolism interrupt normal glucose regulatory mechanisms. Systemic disease states, perinatal stress, and sepsis can predispose an otherwise normal infant to low blood glucose levels. Infants who remain unresponsive to glucose infusion typically have inappropriately high circulating insulin levels for a given blood glucose level. Hyperinsulinemia should be suspected in any infant or child younger than 1 year of age with persistent hypoglycemia. There are heterogeneous causes for hyperinsulinemic hypoglycemia, but the most common historical cause in infancy is nesidioblastosis, which is characterized by uncontrolled development of the pancreatic endocrine tissue that functions abnormally during infancy.^{188,189} Clinically, these cells secrete inappropriately high amounts of insulin, causing clinical hypoglycemia in infants. Two distinct histologic lesions appear to be responsible for congenital hyperinsulinism. Mutations in the beta cell K_{ATP} channel genes may lead to

either focal, adenomatous hyperinsulinism or diffuse hyperinsulinism; both genotypes lead to phenotypic hypoglycemia if left untreated.

Infants with congenital hyperinsulinism usually become symptomatic from hypoglycemia within the first few hours or days of life. These infants commonly present with neurologic symptoms such as lethargy or generalized seizures and have corresponding fasting blood glucose levels less than 40 mg/dL. The diagnosis of hyperinsulinemia is supported by the clinical features of the Whipple triad, which includes (a) neurologic changes with fasting or activity, (b) fasting blood glucose levels less than 40 to 50 mg/dL, and (c) neurologic symptoms reversed by the administration of glucose. The diagnosis is made by demonstrating inappropriately high levels of circulating insulin for a given level of blood glucose. An insulin (IU/mL) to glucose (mg/dL) ratio that is greater than 0.5 in a fasting patient is consistent with hyperinsulinemic hypoglycemia. In infants and children, an absolute insulin level greater than 5 IU/mL in the presence of a blood glucose less than 40 mg/dL is diagnostic. Ketone body production is impaired in infants with congenital hyperinsulinism.

The initial management of a hypoglycemic infant with congenital hyperinsulinism is to provide adequate glucose concentrations to prevent permanent neurologic injury. Dextrose-containing intravenous solutions are titrated to maintain blood glucose levels greater than 40 mg/dL and may require a central venous catheter. The short-term administration of somatostatin analogues to increase blood glucose levels in hyperinsulinemic states has been demonstrated to be useful.¹⁹⁰ Other pharmacologic agents used to reduce insulin levels and raise blood glucose concentration include diazoxide (15 mg/kg daily). The use of streptozocin to control hyperinsulinemia most often is reserved for adults with metastatic islet cell carcinoma and is not widely used in infants because of the potential side effects.

Following initial control of blood glucose and clinical confirmation of hyperinsulinemia, operative intervention should be considered as a means of providing definitive control of hypoglycemia. Diagnostic imaging using CT scan imaging, MRI, or more recently,¹⁸ F-FDOPA PET scanning may be useful either to identify or to exclude a focal lesion.¹⁹¹ Localization of focal lesions is important in that this approach may lead to effective glucose control with selective partial pancreatectomy and allow for preservation of normal pancreatic tissue and function.^{192,193}

Operatively, the abdomen is explored thoroughly, and the entire pancreas must be visualized. Preoperative localization data guided by intraoperative ultrasound and frozen section analysis may identify focal lesions amenable to partial resection. In the absence of a focal lesion, the infant is presumed to have diffuse islet cell hyperplasia. In this setting, the general operative strategy is total or near-total pancreatectomy.¹⁹⁴ Lesser procedures such as subtotal (80%) pancreatectomy do not effectively treat diffuse congenital hyperinsulinism, and recurrent hypoglycemia places the infant at risk for hypoglycemic encephalopathy. Near-total pancreatectomy involves resection of the distal 95% of the gland with preservation of the spleen. The entire distal pancreas, including the uncinate process, is resected, leaving a small rim of pancreatic tissue adjacent to the duodenum (Fig. 107.58). Total pancreatectomy is usually reserved for persistent or recurrent hypoglycemia following lesser procedures. Near-total pancreatectomy controls hypoglycemia in 90% of infants with diffuse congenital hyperinsulinism. The remaining infants with persistent hypoglycemia may require further pancreatic resection. With extensive pancreatic resection, the typical postoperative course is a transient period of hyperglycemia with subsequent stabilization of blood glucose levels. Pancreatic exocrine function is ablated, and oral replacement therapy is required. Despite clinical remission following resection, however, diabetes mellitus may occur as a long-term consequence in children treated either medically or surgically for diffuse congenital hyperinsulinism.¹⁹⁵ Therefore,

FIGURE 107.58. Illustration of the various degrees of pancreatic resection.

these infants need long-term metabolic follow-up for both pancreatic endocrine and exocrine function.

CHAPTER 108 ■ THE PEDIATRIC GENITOURINARY SYSTEM

EUGENE MINEVICH AND CURTIS A. SHELDON

KEY POINTS

- 1 The nephric system develops progressively through three stages.
- 2 Horseshoe kidney is the most common type of renal fusion and occurs in 0.25% of the population.
- 3 Renal cystic disease, congenital or acquired, is one of the most common causes of the pediatric abdominal mass.
- 4 Multicystic dysplastic kidney is the most common type of renal cystic disease.
- 5 The ureteropelvic junction is the most common site of obstruction in the urinary tract and the most common cause of neonatal hydronephrosis.
- 6 Ureteral duplication is the most common anomaly of the urinary tract.
- 7 The incidence of vesicoureteral reflux in otherwise normal children is approximately 1%; the incidence is up to 40% in patients undergoing evaluation for urinary tract infection.
- 8 Epispadias in boys consists of a dorsally placed urethral meatus, and the degree of penile deformity is related to the extent of the meatal displacement.
- 9 Posterior urethral valves are the most common obstructive urethral lesions in male infants and consist of a membrane or mucosal leaflet within the prostatic urethra.
- 10 Descent of the testis from its original position near the kidney into the cooler scrotum is necessary for its normal development and production of fertile sperm. True undescended testes fail to reach the scrotum despite following a normal line of descent.
- 11 Prepubertal testis tumors account for approximately 2% of all testicular tumors, with a peak patient age of approximately 2 years.

THE NEPHRIC SYSTEM

- 1 The nephric system develops progressively through three stages. The initial stage, *the pronephros*, disappears completely by the fourth week of embryonic life. *The mesonephros*, the second stage, degenerates as well, although part of its system becomes associated with the reproductive system. The caudal portion of the mesonephric duct, which communicates with the cloaca, forms a ureteral bud between the fourth and sixth weeks of gestation. The cranial portion of the ureteral bud joins with the metanephric blastema, branching into the renal pelvis and the calyces and inducing nephron formation during the final stage of development, *metanephros*. The kidneys undergo ascent and rotation before assuming their final position.

ANOMALIES OF THE KIDNEY

Supernumerary Kidney

The supernumerary kidney is a very rare anomaly of the urinary system and represents a distinct extra kidney (or kidneys). Embryologically, an additional ureteral bud develops a separate metanephric mass, resulting in the formation of an extra kidney, which is usually caudal to the dominant kidney. This anomaly is usually an incidental finding on abdominal imaging for unrelated reasons, although some adults may occasionally present with abdominal pain, hypertension, or symptoms of urinary tract infections (UTIs).

Renal Agenesis

Absence of a ureteral bud or its failure to join the metanephric blastema results in renal agenesis. A bilateral anomaly occurs

in approximately 1 per 4,000 births (*Potter syndrome*). This is manifested by characteristic faces, pulmonary hypoplasia, and orthopedic abnormalities.¹ These infants are stillborn or rapidly die of respiratory failure.

The incidence of unilateral renal agenesis is about 1 in 1,200 births. The ipsilateral ureter is absent in more than 50% of cases, although an adrenal gland is usually present. The most common contralateral anomalies are vesicoureteral reflux (30%), renal malrotation, or renal ectopia (15%). Genital anomalies are more often observed in girls (25% to 50%) than in boys (10% to 15%); malformations of the rectum, anus, and lower spine frequently occur in both sexes. Other associated congenital anomalies may involve the cardiovascular, gastrointestinal, or musculoskeletal systems. Unilateral renal agenesis is usually asymptomatic and found incidentally.

Renal Ectopy

Failure of the *metanephros* to ascend leads to an ectopic kidney, which occurs in about 1 in 1,100 people. An ectopic kidney may be on the ipsilateral side (*simple ectopy*) or on the contralateral side (*crossed ectopy*) with or without fusion. The adrenal gland develops separately from the kidney and is therefore found in its normal position, despite anomalies in renal position. Further classification of renal ectopia is based on the position of the kidney in the retroperitoneum: abdominal, lumbar, or pelvic kidney. Rarely, the kidney is located above the ipsilateral diaphragm (*intrathoracic kidney*) because of delayed closure of the diaphragm or accelerated kidney ascent.

Most ectopic kidneys are clinically asymptomatic and detected incidentally. Almost half of ectopic kidneys have hydronephrosis secondary to malrotation, aberrant renal vessels compressing the renal pelvis, or ureteropelvic junction (UPJ) obstruction.² If surgical correction of the obstructed kidney is

required, the anomalous renal vasculature may be important. Ectopic kidney function should be preserved because the contralateral kidney is abnormal in up to 50% of patients, with hydronephrosis or vesicoureteral reflux (VUR) being the most common abnormality. Genital anomalies have been reported in 15% to 45% of patients with renal ectopia.

Horseshoe Kidney

- 2 Horseshoe kidney is the most common type of renal fusion and occurs in 0.25% of the population. Patients with Turner syndrome and trisomy 18 have a significantly higher incidence. The anomaly consists of two renal masses connected by the isthmus at the midline, usually at the lower poles. The isthmus, which consists of renal parenchyma or fibrous tissue, usually lies just below the junction of the inferior mesenteric artery and aorta and anterior to the great vessels. The pelvises and ureters of horseshoe kidney are usually anteriorly placed, crossing the isthmus ventrally.

The horseshoe kidney does not usually produce symptoms unless it is associated with other anomalies. The most commonly associated abnormality is VUR and UPJ obstruction, which can lead to UTI or urolithiasis, with corresponding symptomatology. If surgical repair of UPJ obstruction is required, a standard dismembered pyeloplasty with or without division of the renal isthmus is recommended. The retroperitoneal flank approach is usually successful, but the surgeon should be prepared for a transperitoneal approach as well. The incidence of Wilms tumor seems to be increased in patients with horseshoe kidney.³

Cystic Disease of the Kidney

- 3 Renal cystic disease, congenital or acquired, is one of the most common causes of pediatric abdominal masses. Several classifications have been proposed, based on the clinical or radiologic presentation, pathologic studies, and genetic associations.⁴

Autosomal recessive ("infantile") polycystic kidney disease results from dilated collecting ducts and has a spectrum of severity, with the severest forms appearing in infancy. This congenital disorder affects both kidneys and liver (ranging from biliary ectasia to congenital hepatic fibrosis). The affected infant usually presents with large flank masses. Renal ultrasound (RUS) demonstrates enlarged, homogeneously hyperechogenic kidneys. Most children develop progressive renal and/or hepatic failure.

- 4 *Multicystic dysplastic kidney (MCDK)* is the most common type of renal cystic disease. This anomaly represents a severe form of renal dysplasia with complete replacement of renal parenchyma by different-sized cysts (Fig. 108.1). RUS is usually definitive in making the correct diagnosis, although renal scintigraphy is necessary to demonstrate the absence of renal function in the involved kidney and occasionally differentiate MCDK from severe obstructed hydronephrosis. The high incidence of VUR in the solitary functioning contralateral kidney (18% to 43%) makes a voiding cystourethrogram (VCUG) an essential part of the evaluation. Involution of MCDK may occur to the point that the involved kidney disappears from subsequent sonograms. Potential long-term sequelae of retained MCDK, including hypertension, infection, and pain, are very rare. Sporadic reports of renal cell carcinoma and Wilms tumor in MCDK raise concern of the persistent potential for malignant degeneration in the dysplastic kidney. Patients with MCDK should be followed with ultrasonic surveillance, especially in early childhood.⁵ Nephrectomy is reserved for the symptomatic child, the patient with equivocal radiologic appearance, or MCDK that fails to regress.

FIGURE 108.1. Multicystic dysplastic kidney.

Ureteropelvic Junction Obstruction

- 5 The UPJ is the most common site of obstruction in the urinary tract and the most common cause of neonatal hydronephrosis. The pathogenesis of this disorder is variable. Of the intrinsic factors, the adynamic segment is associated most often with classic UPJ obstruction. This obstruction is thought to be a congenital absence or abnormal arrangement of the muscular fiber at the transition zone of the upper ureter and renal pelvis leading to failure of peristaltic wave propagation. Extrinsic causes include fibrous bands, aberrant accessory vessels, and various organ-compressing factors. Most cases of UPJ obstruction are diagnosed in utero and such patients are initially asymptomatic. Some children present with abdominal or flank pain, hematuria, or UTI. Occasionally, previously asymptomatic UPJ obstruction may be discovered in the patient with renal injury following relatively minor abdominal trauma.

RUS is the test of choice to determine the degree of renal pelvic dilatation, parenchymal thickness, and associated abnormalities of the bladder and the ureter. Diuretic renography and occasionally Whitaker antegrade pressure perfusion studies are necessary to confirm UPJ obstruction. The VCUG and occasional excretory urogram (intravenous pyelogram [IVP]) may define anatomic details (Fig. 108.2). Retrograde pyelography is used to rule out other causes of obstruction and is usually performed just before surgery.

A dismembered pyeloplasty, with removal of an adynamic segment, remains the surgical treatment of choice because it provides dependant drainage of the renal pelvis. With utilization of optical magnification and careful attention to surgical technique, a successful outcome should be expected in over 95% of cases.⁶ Laparoscopic pyeloplasty can be performed in older children.

ANOMALIES OF THE URETER

Ureteral Duplication

- 6 Ureteral duplication is the most common anomaly of the urinary tract. Early branching of the single ureteral bud results in *incomplete (partial) duplication* with a single ureteral orifice and bifid proximal ureters (1 in 125 individuals). An accessory ureteral bud creates *complete duplication* (1 in 500 individuals), with the upper ureter usually inserting into the bladder

FIGURE 108.2. Intravenous pyelogram showing hydronephrosis secondary to ureteropelvic junction obstruction.

more medially and inferiorly than the lower ureter. The upper ureter is more likely to be associated with ectopic insertion, ureterocele, or obstruction, whereas the lower ureter is frequently associated with VUR. Most patients with ureteral duplication are asymptomatic, although they occasionally present with UTI.

Ureteral Ectopia and Ureterocele

The ectopic ureteral orifice lies in a position caudal to the normal insertion of the ureter on the bladder trigone. Ureteral ectopia is much more common in association with complete ureteral duplication. In the boy, ectopic ureteral orifices are most frequently found at the prostatic urethra and even along the course of the male genital ductal system. In the girl, ectopic ureters can be found draining into the bladder neck, urethra, vagina, or even the uterus. Boys with bilateral anomaly and girls with termination of an ectopic ureter below the external urinary sphincter usually present with urinary incontinence.

Ureteroceles are congenital cystic dilations of the distal ureter. Those associated with a single ureter (simple ureterocele) are usually located in an orthotopic trigonal position. Ureteroceles found in association with duplicated ureters usually drain the upper pole kidney and are located in an ectopic position. Ectopic ureteroceles are commonly associated with obstruction and varying degrees of dysplasia of the affected renal segment. Decompression of the obstructed renal moiety from above (ureteropyelostomy) or from below (excision of ureterocele with ureteral reimplantation) is usually successful. Transurethral puncture of a ureterocele is usually reserved for infants, whereas a severely dysplastic moiety can be managed by partial nephrectomy. Large ureteroceles obstructing other renal moieties and the bladder neck will most likely require secondary procedures to restore normal urinary tract anatomy.⁷

Vesicoureteral Reflux

7 Vesicoureteral reflux refers to the retrograde passage of urine from the bladder into the ureter. The incidence of VUR in otherwise normal children is approximately 1%; a much higher incidence of up to 40% is reported in patients undergoing evaluation for UTI. A significant familial association has been encountered. A sufficient tunnel length of submucosal ureter is the most important component of the competent ureterovesical junction. This provides a predominantly passive valve mechanism compression of the ureter, preventing retrograde passage of urine. Marginal tunnel pressure can be made to reflux primarily or secondarily because of loss of compliance of the valve roof (during UTI), structural weakness of the detrusor floor (bladder diverticulum, ureterocele), or excessively high intravesical pressure caused by neurovesical dysfunction or bladder outlet obstruction. VUR is graded according to the International Classification System based on the proximal extent of retrograde urine flow, ureteral and pelvic dilatation, and the resultant anatomy of the calyceal fornices.

Reflux-induced renal injury is usually caused by the association of VUR with UTI and may range from clinically silent focal scar formation to generalized scarring and renal atrophy (reflux nephropathy) with hypertension and even end-stage renal failure. Children of either sex should be investigated at the time of the initial infection. The diagnosis of VUR is accomplished by cyclic VCUG, with either contrast medium or isotope (Fig. 108.3). Imaging of the upper tracts (kidneys and ureters) is extremely important and can be accomplished by ultrasonography, isotope renography, or, rarely, intravenous urography. Ultrasonography is helpful in quantifying renal growth or atrophy, whereas isotope renography is particularly sensitive in detecting focal scarring. Patients with voiding dysfunction should be considered strongly for urodynamic studies.

Because the submucosal ureter tends to lengthen with age, the ratio of tunnel length to ureteral diameter increases, and the propensity for reflux may disappear. In general, a lower reflux

FIGURE 108.3. Voiding cystourethrogram of bilateral vesicoureteral reflux.

grade correlates with a better chance of spontaneous resolution. Nonoperative management of VUR (which is successful in most patients) requires prevention of UTI with suppression antibiotics, treatment of symptomatic voiding dysfunction, and long-term strict surveillance. Patients with breakthrough UTIs, significant renal injury, high-grade reflux, or pubertal age or those who fail to respond to 4 to 5 years of suppression therapy may require surgical correction. The principle of open ureteral reimplantation is the creation of a capacious subepithelial tunnel with the ratio of its length to ureteral diameter equal to 5:1. In general, excellent results are attained with most open intravesical or extravesical procedures. The extravesical approach, which preserves the integrity of the bladder lumen and doesn't require a ureteral anastomosis, eliminates postoperative hematuria, minimizes bladder spasms, decreases the risk of postoperative obstruction, and shortens hospital stay.⁸ Since the initial report of successful endoscopic subureteral injection of polytetrafluoroethylene (Teflon) for correction of VUR, this minimally invasive technique has been widely used worldwide with different injectable materials. The only injectable substance with Food and Drug Administration approval is dextranomer/hyaluronic acid copolymer (Deflux). This substance is biodegradable, has no immunogenic properties, and seems to have no potential to cause malignant transformation.⁹

Megaureter

The term *megaureter* refers to an enlarged ureter, of which there are four categories: refluxing, obstructing, refluxing or obstructing, and nonrefluxing or nonobstructing, with an additional subdivision of each group into primary or secondary. Most patients are asymptomatic with an incidental finding of hydroureteronephrosis on screening renal ultrasound. The most common clinical presentation is UTI. The VCUG is necessary to rule out VUR, although its presence does not exclude the possibility of a coexistent obstruction. Diuretic renography is helpful to establish the presence of ureteral obstruction, which is usually at the level of the ureterovesical junction.

Megaureter secondary to severe VUR or obstruction is usually managed with ureteral reimplantation to prevent deterioration of renal function. Reduction of ureteral caliber by excision of the distal redundant ureter to achieve a satisfactory antireflux mechanism is usually necessary. Patients without reflux or obstruction may demonstrate radiographic improvement of the megaureter with preservation of renal function without surgical intervention. Therefore, initial nonoperative management with close follow-up of patients with nonobstructing or nonrefluxing megaureters is advisable.¹⁰

VESICourethRAL SYSTEM

The cloaca forms from the blind caudal end of the hindgut. The division of the cloaca by the urorectal septum into a ventral portion (the urogenital sinus [UGS]) and a dorsal portion (the rectum) is completed by the seventh week of gestation. Simultaneously, the mesodermal growth of the lower abdominal wall separates the umbilical cord from the genital tubercle. The mesonephric duct and ureteral bud have independent opening sites. The mesonephric duct (which will become the ejaculatory duct) migrates downward and medially, while the opening of the ureteral bud (which will become the ureteral orifice) migrates upward and laterally. The UGS can be divided into two segments at the point where the müllerian ducts join the dorsal wall of the UGS. The ventral portion forms the bladder, part of the prostatic urethra in the male, and the entire female urethra. The caudal portion gives rise to a portion of the prostatic and the entire membranous urethra in males and forms the lower part of the vagina and the vaginal vestibule in females.

ANOMALIES OF THE BLADDER

Urachal Abnormality

Embryologically, the urachus represents the apical attachment of the cloaca to the allantois. During fetal development it is obliterated and eventually represented by a fibrous retroperitoneal cord extending from the dome of the bladder to the umbilicus. Symptomatic urachal anomalies are rare and clinical syndromes most often arise from a patent urachus or a urachal cyst. The former condition is suggested by a persistently wet umbilicus and can occur in patients with bladder outlet obstruction. Excision of the urachus with bladder closure is usually necessary.

The urachal cyst is an inclusion cyst lined with transitional epithelium. If infected, it can present with abdominal pain and tenderness as well as fever, nausea, and leucocytosis, closely mimicking the acute abdomen. Radiologic evaluation should include abdominal US and/or computed tomography (CT). The infected urachal cyst is best managed by initial drainage of the abscess and delayed excision of the urachal remnant. Exploratory laparotomy is indicated if signs of peritonitis are present¹¹ (Algorithm 108.1).

Exstrophy–Epispadias Complex

The overgrowth and delayed rupture of the cloacal membrane prevents medial mesenchymal migration and proper lower abdominal wall development. Depending on the extent of the infraumbilical defect and the stage of development at which rupture occurs, bladder exstrophy, epispadias, or cloacal exstrophy results.

8 Epispadias in boys, as an isolated defect, consists of a dorsally placed urethral meatus and the degree of penile deformity is related to the extent of the meatal displacement. Most often, epispadias is associated with exstrophy of the bladder (Fig. 108.4). This defect usually involves pubic diastasis with separation of the rectus abdominis muscles, inguinal hernias, and anterior displacement of the anus. Male external genitalia have a characteristic epispadiac appearance, while females have a bifid clitoris with a stenotic and short vagina. Complete primary closure of the bladder plate with simultaneous repair of epispadias within the first 72 hours of life is the most appropriate treatment of this complicated anomaly.¹²

Cloacal exstrophy is the most severe defect that can occur in the formation of the ventral abdominal wall. Anatomically, there is exstrophy of the shortened hindgut or cecum, which displays its bulging mucosa between the two hemibladders. There is no

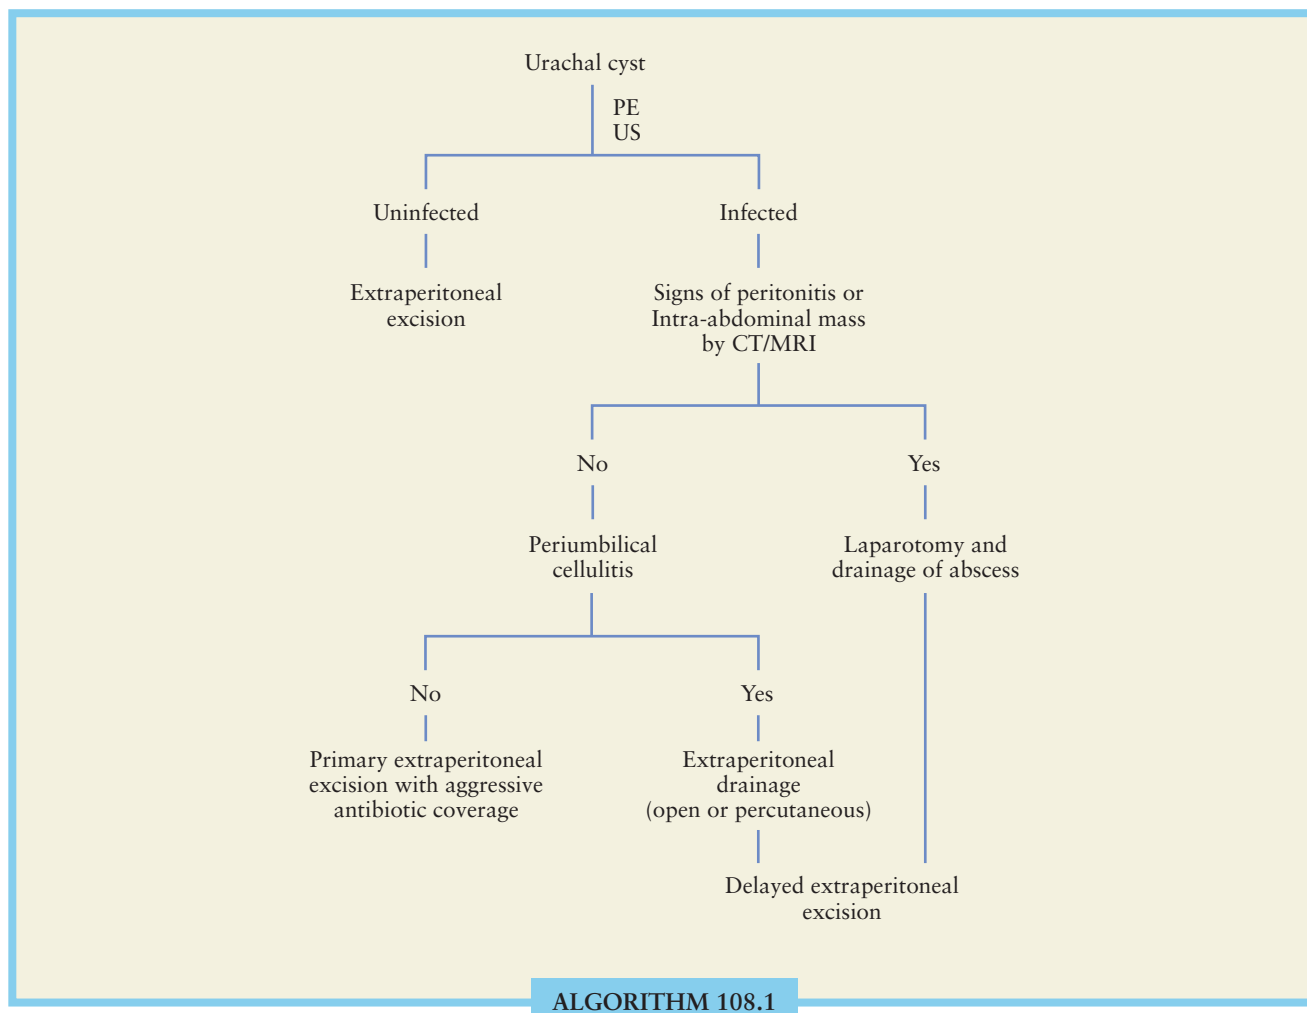

FIGURE 108.4. Newborn boy with classic bladder exstrophy.

ALGORITHM 108.1. Algorithm of surgical management of urachal cyst. PE, physical examination; US, ultrasound. (Adapted from Minevich E, Wacksman J, Lewis AG, et al. The infected urachal cyst: primary excision versus a staged approach. *J Urol* 1997;157:1869.)

anus or rectum, and an omphalocele is present (Fig. 108.5). The initial surgical approach (in the neonatal period) includes closure of the omphalocele, separation of the bladder from the bowel, and closure of the bladder. Considerable reconstructive surgery remains to be done later to restore acceptable anatomic appearance and functioning urinary and intestinal tracts.

Neurogenic Bladder

An abnormal spinal column development affecting spinal cord function (myelodysplasia) is the most common cause of neuro-

genic bladder (NGB) in children. Myelomeningocele (MM) accounts for over 90% of open spinal dysraphic states. Bladder dysfunction usually results in urinary incontinence, although the poorly compliant bladder with leak point pressure over 40 cm H₂O may cause VUR and hydronephrosis, leading to deterioration of renal function.¹³ Presumably at this point the ureterovesical junction can no longer protect the transmission of this pressure to the upper tracts. Urinary continence depends on bladder capacity and bladder outlet (bladder neck and urethral sphincter) resistance. The most important contribution affecting management of these children was the introduction of clean intermittent catheterization

FIGURE 108.5. Diagram depicting cloacal exstrophy.

FIGURE 108.6. Bladder augmentation employing an intestinal segment. **A:** The bladder is opened as a “clam shell.” **B:** The intestinal segment is detubularized by longitudinal incision along the antimesenteric border. A cup-patch is fashioned by suturing one edge of the resultant rectangle to itself. **C:** The cup-patch is sutured to the remnant bladder plate. **D:** Final appearance. (CIC) to facilitate timely bladder emptying. Evaluation of infants with urodynamic studies, RUS, and VCUG identifies those ultimately at risk for renal damage.

The primary goal in children with NGB is maintenance of safe intravesical pressure, the ultimate achievement of urinary continence, and preservation of renal function. If anticholinergic therapy with or without CIC is unsuccessful in achieving these goals, surgical reconstruction is necessary. Owing to the high incidence of upper tract deterioration with time and the significant sequelae of altered body image following cutaneous urinary diversion, incontinent diversion is no longer considered an acceptable alternative to reconstruction in the pediatric population. The goals of reconstructive surgery are to achieve a large-capacity, low-pressure reservoir; adequate bladder outlet resistance; and easy access for catheterization. A variety of donor tissue sources including bowel segments, stomach, or ureter are available for bladder augmentation (Fig. 108.6). Potential complications of enterocystoplasty include electrolyte abnormalities, spontaneous perforation of the bowel segment, and tumor formation. Bladder outlet resistance can be increased by bladder neck reconstruction, implantation of an artificial urinary sphincter, urethral or bladder neck suspension, submucosal injection of collagen, or a combination of these procedures. A Mitrofanoff neourethra (appendiceal or ileal) is usually necessary to provide bladder access for decompression and continence, and is highly successful in even the most devastating cases.¹⁴

Significant neurogenic bladder is frequently accompanied by refractory fecal incontinence. This may severely compromise care with respect to UTI, incontinence, and achieving independent self-care. When preoperative conventional therapy (dietary modification, timed toileting, cathartics, bulking agents, and enemas) is unsuccessful to control complete evacuation of the colon, an antegrade continence enema (ACE) procedure, performed through a continent cecostomy utilizing appendix or tapered ileum, is a viable option. The ACE procedure has been successfully utilized in the management of intractable fecal incontinence, even in the most debilitating childhood recto-urogenital anomalies.¹⁵

ANOMALIES OF THE URETHRA

Posterior Urethral Valves

- 9 Posterior urethral valves are the most common obstructive urethral lesions in male infants and consist of a membrane or mucosal leaflet within the prostatic urethra. The diagnosis is usually suspected in neonates because of abnormal findings of prenatal hydronephrosis (bilateral hydronephrosis, distended bladder) and oligohydramnios. Some of them are found to have flank masses, ascites, and urinary retention. Older children usually present with voiding symptoms, UTI, or hematuria. VCUG is diagnostic in most cases (Fig. 108.7), although cystoscopy may be necessary in an equivocal setting. Patients with significant bilateral hydronephrosis should be screened for renal insufficiency, and nuclear

FIGURE 108.7. Voiding cystourethrogram showing dilated posterior urethra secondary to posterior urethral valves.

scintigraphy may be indicated to rule out ureteral obstruction and/or renal dysplasia.

Other than temporary urinary drainage with a urethral catheter (feeding tube), in critically ill patients primary endoscopic valve ablation is the preferred approach and may be accomplished safely in most instances. Initial temporary cutaneous vesicostomy is useful in occasional circumstances. High upper urinary tract diversion may on rare occasion be necessary in infants who demonstrate a rising creatinine despite a lower tract drainage. Long-term follow-up is necessary with special attention directed to the possible development of a poorly compliant, high-pressure bladder.¹⁶ Careful urodynamic evaluation and timely treatment of the “valve bladder” with anticholinergics, CIC, and very selective vesical reconstruction (including enterocystoplasty) as well as prevention of UTI ensure the best chance for successful prevention and/or management of chronic renal failure.

Hypospadias

Hypospadias is a common congenital defect resulting from incomplete tubularization of the urethral plate and closure of the genital folds. The cause of this anomaly is unknown, but is probably related to inadequate androgenization before the 20th week of gestation. The meatus may be located anywhere from the perineum to the glans penis, although in over 85% of cases it is distal to the midshaft (Fig. 108.8). Typically, the ventral prepuce is deficient and ventral penile chordee occurs more frequently with proximal hypospadias.

Principles of hypospadias repair include meticulous surgical technique with sufficient optical magnification to advance the urethral meatus to a normal glanular position and to correct penile chordee if necessary. Numerous operations have been described for surgical correction of hypospadias and the surgeon treating this anomaly should be familiar with all possible

FIGURE 108.8. Coronal hypospadias.

approaches. An outpatient one-stage procedure can be safely performed after 6 months of age in most cases. While local skin flaps are utilized in repairs of more distal hypospadias, vascularized preputial pedicle flaps or a tube-graft may be necessary in more proximal hypospadias. Patients with hypospadias should not be circumcised until they are evaluated by an experienced pediatric urologist. If sufficient penile skin is not available, bladder mucosal or buccal mucosal grafts can be utilized. Although rare, complications after hypospadias surgery include urethrocutaneous fistula, urethral strictures, and meatal stenosis.

GENITAL SYSTEM

The development of the genital tract follows a sequential pattern and is initially determined by chromosomal composition of the fertilizing sperm, resulting in 46,XY (male genotype) or 46,XX (female genotype) zygote. The genetic material necessary for the development of the testis is found on the short arm of the Y chromosome and is known as the SRY gene. The presence of this gene determines an aggregation of primitive indifferent germ cells and Sertoli cells into the testicular cord. Thereafter, the endocrine effect on sexual development is most crucial in male phenotype development. Testosterone, produced by Leydig cells, results in *wolffian duct* (remnant of mesonephric duct) differentiation into the vas deferens, the seminal vesicles, and the epididymis. In addition, testosterone converted at the end-organ target sites to dihydrotestosterone (DHT) by 5 α -reductase regulates the virilization of the urogenital sinus and external genitalia at around the ninth week of gestation. Only at this point, the previously indifferent genital tubercle starts to differentiate into a penis while the genital swelling fuses to form the scrotum. At the same time, müllerian-inhibiting substance (MIS) produced by testicular Sertoli cells results in an almost complete regression of the *müllerian ducts*.

In the absence of the SRY gene, the primitive gonads differentiate into an ovary. The female development of the *müllerian (paramesonephric)* duct system into fallopian tube, uterus, and cervix; feminization of the external genitalia; and involution of the *wolffian ducts* are automatic processes in the absence of testosterone and MIS.

AMBIGUOUS GENITALIA

The term *ambiguous genitalia* refers to genitalia in the spectrum of sexual development that are not clearly male or female. This situation represents a true medical and social emergency. Rapid but careful determination of the genetic composition, gonadal sex, and genitourinary anatomy of the affected newborn is essential to enable gender assignment, acceptance of the child by the family, and ultimately surgical reconstruction.

Patients with ambiguous genitalia can be divided in four categories: female and male pseudohermaphroditism, true hermaphroditism, and gonadal dysgenesis. Complete evaluation of the infant with ambiguous genitalia should include the following:

1. Thorough physical examination (special attention to palpable gonads, phallic structure, vaginal orifice, and anus)
2. Complete family history (genital anomalies in other family members, unexplained neonatal death in previous children)
3. Evaluation of the pregnancy (especially maternal exposure to androgenic agents)
4. Blood karyotype
5. Biochemical evaluation (serum electrolytes, adrenal steroids and precursors, serum gonadotropins, and testosterone)
6. Radiologic evaluation (renal and pelvic US, genitogram)

Occasionally, diagnostic laparoscopy and gonadal biopsy are necessary to guide the gender assignment. After the chromosomal and gonadal composition is established, sex assignment is

determined, based mostly on the potential for sexual function. Surgical reconstruction is aimed at matching the external genitalia to the gender assigned to the child and is usually undertaken at 6 to 12 months of age.¹⁷

Female Pseudohermaphroditism

Female pseudohermaphroditism is the largest diagnostic category and, within this category, the leading cause is congenital adrenal hyperplasia (CAH). CAH results from a deficiency in the enzymes responsible for the synthesis of mineralocorticosteroids and glucocorticosteroids, resulting in overproduction of adrenal androgens. A deficiency of 21-hydroxylase represents 95% of patients with CAH. All of these patients are genetic females (46,XX karyotype, ovarian gonads) with masculinization of the external genitalia ranging from an enlarged clitoris to a normal-appearing male phallus with complete labial fusion (Fig. 108.9). These patients are potentially fertile regardless of how severe the degree of virilization.

A high index of suspicion allows for early diagnosis of this condition and initiation of hormonal replacement (glucocorticosteroids and mineralocorticosteroids) to prevent adrenal insufficiency, salt-wasting syndrome, and continued virilization. Because internal müllerian structures are always present, these children are reared as females and feminizing genitoplasty is performed to correct the cosmetic and functional deformities of external genitalia. If the vagina enters the urogenital sinus distally, a cutback or flap vaginoplasty can be combined with clitoroplasty (reduction and relocation of the clitoris with preservation of glanular sensation) and labioplasty in a single procedure. If the vagina enters the urogenital sinus more proximally, a total urogenital sinus mobilization, pedicle skin flap, or segmental bowel interposition vaginoplasty is deferred to a later date.

FIGURE 108.9. Severe masculinization of the external genitalia in a girl with congenital adrenal hyperplasia.

Male Pseudohermaphroditism

Male pseudohermaphrodites are genetic males (46,XY) with decreased virilization of the external genitalia. This anomaly can result from abnormal testosterone synthesis, 5 α -reductase deficiency leading to decreased levels of DHT, and androgen insensitivity syndrome (defect of the androgen receptor). The phallic structure may be inadequate for the male gender role. In this setting, consideration should be given to female gender assignment.

Testicular feminization syndrome (complete androgen insensitivity) is the most common form of male pseudohermaphroditism, although affected individuals appear as normal phenotypic females with a short vagina. They are usually diagnosed at puberty with primary amenorrhea, although infrequently diagnosis is made during routine childhood herniorrhaphy, at which time testes are found. Bilateral gonadectomy is indicated because of an increased risk of gonadoblastoma development in the intra-abdominal testis. It can be delayed until puberty in selected cases. Short vagina can be managed with vaginal dilatation, but vaginal reconstruction or vaginal replacement will be necessary in some patients.

True Hermaphroditism

In this condition, patients have both ovarian and testicular tissue (ovary and testis, ovotestis, or a combination of these). True hermaphroditism is the rarest form of intersex abnormality. The internal genital structures conform with the ipsilateral gonad. The most common karyotype is 46,XX, although mosaicism and a 46,XY karyotype occur as well. The appearance of external genitalia varies widely. After gender is assigned, gonadal tissue of the opposite sex is removed and surgical reconstruction is undertaken.

Mixed Gonadal Dysgenesis

This is the second most frequent cause of genital ambiguity, and the majority of neonates exhibit a 45,XO/46,XY mosaic karyotype. They generally present with a dysgenetic testis on one side and a streak of gonads on the other. The appearance of external genitalia is variable; however, the majority are poorly virilized and consequently most infants will be raised as females. Appropriate genital reconstruction is required. Early gonadectomy is indicated because of the high risk of malignant degeneration (gonadoblastoma, seminoma, and dysgerminoma) of the dysgenetic gonad.

ANOMALIES OF MALE GENITALIA

Anomalies of the Foreskin

At birth, the prepuce is retractable in only 4% of boys. No special care of the uncircumcised penis is required. During the first years of life, spontaneous separation occurs physiologically in most boys secondary to intermittent erections and epithelialization of the inner prepuce. It is unnecessary to retract the prepuce on any routine basis to promote retractability or to hasten physiologic separation. This usually results in pain, bleeding, and, occasionally, paraphimosis.

Much confusion exists as to the indications for neonatal circumcision. The most important arguments are those of custom and tradition. In infants, circumcision may be performed using the Gomco clamp under local penile block. The most important principles of neonatal circumcision are complete lysis of penile adhesions, adequate but not excessive excision of outer and inner preputial layers, hemostasis, and protection of the glans penis.

Truly pathologic phimosis, paraphimosis, and recurrent balanitis are definitive indications for circumcision. It is estimated that as many as 18% of uncircumcised boys may develop one of the aforementioned indications by 8 years of age. Phimosis is a fibrotic contraction of the foreskin preventing its retraction over the glans. This pathologic condition should be differentiated from physiologic phimosis of infancy. Paraphimosis is the entrapment of a phimotic prepuce proximal to the coronal sulcus. The skin ring causes venous congestion initially, but as the condition progresses, arterial occlusion and necrosis of the glans penis may occur. If persistent manual compression does not reduce paraphimosis, emergency circumcision or the creation of a dorsal slit is indicated. Circumcision in infancy undoubtedly prevents cancer of the penis. If the decision is made not to circumcise a male infant, there must be a lifetime commitment to genital hygiene to minimize the risks of developing penile cancer. Circumcision should be encouraged in boys with a history of UTI, VUR, or other urinary abnormalities to decrease the chance of ascending infection. Patients with hypospadias, penile chordee, penile torsion, epispadias, buried penis, or megalourethra are not candidates for routine circumcision. To correct these conditions, a sufficient amount of foreskin must be available.

Cryptorchidism

10 Descent of the testis from its original position near the kidney into the cooler scrotum is necessary for its normal development and production of fertile sperm. Various mechanisms including gubernacular traction and intra-abdominal pressure have been proposed to be responsible for testicular descent, but endocrine factors of the hypothalamic-pituitary-testicular axis also play a major role in this process. Between the 12th and 17th weeks of gestation, the testis undergoes transabdominal migration to a location near the internal inguinal ring. It is not until the seventh month of gestation that transinguinal migration of the testis to its final position takes place.

True undescended testes fail to reach the scrotum despite following a normal line of descent. Ectopic testes follow the usual course of descent until they emerge from the external inguinal ring, but are then misdirected to an ectopic position (superficial inguinal pouch, perineal, femoral, transverse scrotal). While approximately 3.4% of full-term boys have undescended testes, 30% of premature infants have this anomaly. By 1 year of age, the incidence of cryptorchidism is about 1% and remains at this level thereafter. Actually, most cryptorchid testes descending during the first year of life do so within the first 3 months after birth. The diagnosis of cryptorchidism relies upon gentle and patient genital examination. Relaxation of the patient and warming of the examiner's hand aid in successful examination. Reexamination of the child in the cross-legged position may also reveal the gonad. A functional classification that provides a practical approach to therapy is based on whether the testis is palpable or impalpable (20%). While endocrine testing is reliable in predicting bilateral anorchidism, radiologic means including abdominal sonography, computed tomography, magnetic resonance imaging, and gonadal arteriography are inaccurate in localization of nonpalpable testes. Diagnostic laparoscopy will provide diagnosis of vanishing testis by identification of blind-ending spermatic vessels or accurate localization of the intra-abdominal testis in this situation.¹⁸ Undescended testes must be distinguished from retractile testes that may reside above the scrotum but, with careful positioning, can be made to stay within the lower scrotum without continuous traction.

Although the correction of undescended testes eliminates any coexisting inguinal hernia (found in 95% of all cases) and prevents possible testicular injury or torsion (the risk of which is increased in these patients), the central issues in managing these patients revolve around future fertility and the risk of

developing a testicular neoplasm. There is an increased risk of testicular carcinoma in undescended testes, and orchidopexy facilitates self-examination and early detection of the cancer. Because germ cell count of the infant undescended testis deteriorates after 1 year of life, correction of cryptorchidism is indicated between 6 and 12 months of age. For palpable undescended testes, routine inguinal orchidopexy is successful in most patients. For high intra-abdominal testes, testicular microsurgical autotransplantation¹⁹ provides the highest success rate among different surgical options.²⁰

Torsion of the Testis and Appendages

Torsion of the testicle is classified as a surgical emergency because it causes strangulation of gonadal blood supply with subsequent testicular necrosis and atrophy. Testicular salvage is likely if the duration of torsion is less than 6 to 8 hours.²¹ Torsion presenting in the neonatal period most commonly develops prenatally in the spermatic cord proximal to the attachments of the tunica vaginalis (*extravaginal torsion*). Although possible at any age, testicular torsion is most common in adolescents, being distal to the insertion of the tunica vaginalis (*intravaginal torsion*). A bell-clapper deformity predisposes to this condition.

Prenatal torsion presents with a firm, hard scrotal mass that does not transilluminate in an otherwise asymptomatic newborn male. Salvage of the testis is extremely rare,²² but timely surgical exploration is indicated to anchor the contralateral testis, since bilateral (synchronous or asynchronous) neonatal testicular torsion has been described. In older boys sudden onset of severe testicular pain followed by scrotal swelling is the classic presentation of testicular torsion. On physical examination, a swollen, tender testis with shortening of the cord is noticed. If testicular torsion is clinically suspected, an immediate surgical scrotal exploration is indicated. A negative exploration of the scrotum is more acceptable than the loss of a testis that might have been salvaged. In situations with a low suspicion of testicular torsion, scrotal color Doppler US or testicular nuclear scan can be helpful to differentiate torsion from acute epididymitis. At surgical exploration, the testis is untwisted and observed for viability. A frankly necrotic testis is removed, while viable gonads (return of color, return of Doppler flow, signs of arterial blood after incision of tunica albuginea) are fixed to the scrotal wall to prevent subsequent torsion. Exploration and anchoring of the contralateral testis, which can be done through the same incision, is mandatory to prevent its subsequent torsion. Manual detorsion of the torsed testis is usually difficult because of acute pain during manipulation but, if successful (and confirmed by color Doppler US in a patient with complete resolution of symptoms), definitive surgical fixation of the testes should be performed before the patient leaves the hospital as an urgent rather than emergency procedure.

The testicular appendix, a müllerian duct remnant, is the most common genital appendage susceptible to torsion. Although frequently presenting with symptoms similar to testicular torsion, this condition can usually be diagnosed by a finding of a tender focal induration or a blue dot near the upper pole of the testis. Appendix testis torsion is best managed by several days of bed rest and oral preventive antibiotics. If a reliable diagnosis cannot be made, scrotal color Doppler US or even surgical exploration is indicated to rule out testicular torsion.

Prepubertal Testicular Tumor

In boys presenting with a painless palpable scrotal mass, a testicular tumor should be included in the differential diagnosis. **11** Prepubertal testis tumors account for approximately 2% of all testicular tumors, with a peak patient age of approximately 2 years. The most common lesion is a yolk sac tumor, which is a variant of embryonal cell carcinoma. When spread occurs, it

is usually a hematogenous spread to the lungs and, less commonly, lymphatic spread to the retroperitoneal nodes. Scrotal US is usually definitive in visualizing an intratesticular mass, while abdominal and chest CT scans are necessary for metastatic evaluation. Tumor markers (α -fetoprotein and β -human chorionic gonadotropin) are helpful for initial evaluation and during follow-up. In young children, prognosis is excellent and the radical inguinal orchiectomy is the initial treatment. Retroperitoneal lymph node dissection and multi-drug chemotherapy are necessary in cases of disseminating disease. In the absence of metastasis and/or elevated tumor marker levels, the applicability of these treatment modalities remains controversial.

Varicocele

Varicocele is a dilation of the veins of the spermatic cord and is reported to occur at a 15% incidence in adolescent boys, which correlates with that in the general male population. In the majority of adolescents the varicocele is grade I, while in 35% it is grade II or III. Varicocele is generally visible or palpable in the upright position. Most urologists agree that scrotal discomfort and ipsilateral testicular growth failure are reliable indications for varicocele surgery in this population. Additionally, some authors have advocated surgical repair in patients demonstrating a progressive increase in varicocele size, bilateral varicoceles, or a large varicocele associated with a change in testicular consistency. Incisional surgery with an inguinal, retroperitoneal, or modified approach is the basis of varicolectomy in adolescents. The optical magnification allows reliable identification and preservation of the testicular artery and lymphatics during ligation of the venous channels. As a result, the postoperative development of hydrocele or recurrence of the varicocele may be prevented.²³

VAGINAL ANOMALIES AND UROGENITAL SINUS MALFORMATIONS

The urogenital sinus is apparent by 6 weeks of gestation. After it receives the fused müllerian ducts, the distal portion of the UGS forms the lower one third of the vagina, while the fused müllerian ducts form the upper two thirds of the vagina and uterus. Although most vaginal anomalies occur in conjunction with intersex disorders, isolated vaginal anomalies or those occurring in association with a urogenital sinus are also seen (Fig. 108.10). Vaginal agenesis may occur in isolation or as a component of the Mayer-Rokitansky syndrome, which refers to normal phenotypic females with vaginal and occasional uterine dysgenesis. Because the distal vagina is normally formed in most of these patients, the diagnosis is not usually made until puberty, at which time the patient presents with amenorrhea. Approximately one third of these patients have urologic anomalies, the most common being unilateral renal agenesis. Vaginoplasty is indicated in almost all patients and depends on the anatomy present. Several techniques using tubularized skin flaps, skin grafts, and bowel segments have been described for vaginal reconstruction.²⁴ Careful preoperative counseling and evaluation of the patient's and parents' motivation are essential for a good result since long-term vaginal dilatation is occasionally required until the patient is old enough to participate in sexual intercourse.

UGS anomalies occur because of a failure of the urethra and the vagina to separate. These children have two perineal openings, including the anus, because the rectum is usually normal. Many of these girls have some degree of bladder dysfunction and CIC may be necessary. If CIC of the bladder is not possible, temporary vesicostomy may be indicated. To sep-

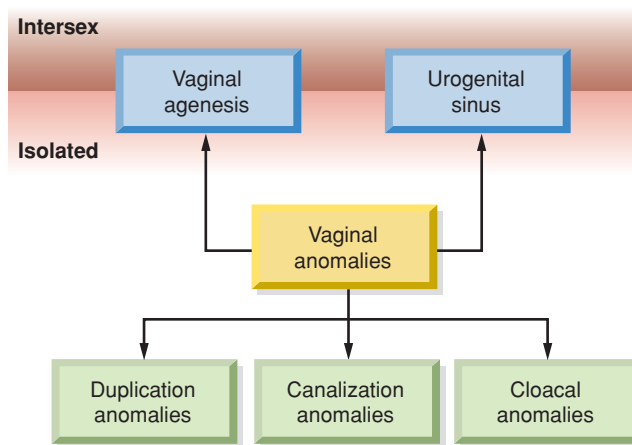

FIGURE 108.10. Classification of vaginal anomalies. (Reproduced with permission from Sheldon CA. Imperforate anus, urogenital sinus and cloaca. In: Kelalis PP, King LR, Belman AB, eds. *Clinical Pediatric Urology*. Philadelphia: WB Saunders; 2000.)

arate the urethral and vaginal orifices, urethral lengthening or vaginal pull-through procedures are required.^{24–26}

OTHER GENITOURINARY DISORDERS

Eagle-Barrett Syndrome

The Eagle-Barrett syndrome, also referred to as prune-belly syndrome (PBS), is a set of genitourinary malformations with a deficiency or absence of the abdominal wall musculature accompanied by a broad spectrum of associated organ system anomalies. It was theorized that delayed canalization of the urethral membrane resulted in a temporary total urinary obstruction causing massive dilatation of the ureters, a large bladder frequently associated with a patent urachus, and a dilated proximal urethra with a hypoplastic prostate. The wrinkled, prunelike skin of the abdominal wall in the newborn is a characteristic manifestation. Renal dysplasia occurs frequently and in severe cases is associated with pulmonary hypoplasia, resulting in stillbirth or death in the neonatal period. Bilateral cryptorchidism with intra-abdominal testes is a characteristic feature of PBS. Extraurinary problems are associated with this syndrome in 73% of patients and usually involve defects of the cardiovascular, musculoskeletal, respiratory, or central nervous systems.²⁷ Since the dilatation of the urinary tract is usually nonobstructive, a favorable outcome in these patients can be expected with a conservative approach of observation, prevention of UTI, and surgical drainage, with reconstruction only being performed when absolutely required.

Urologic Implications of Imperforate Anus

Anorectal malformations (ARMs) encompass a broad spectrum of abnormalities of termination of the hindgut and urogenital sinus, ranging from the simple covered anus to complex cloacal malformations involving the gastrointestinal, urinary, and genital tracts. Morbidity and mortality in these cases are largely attributed to associated structural and functional genitourinary anomalies, ranging from vesicoureteral reflux (57%) to renal dysplasia and agenesis (65%). Therefore, neonatal screening with renal US and VCUG is essential in all patients with ARMs.²⁸ The assessment of bladder function is also critical because of a reportedly high incidence of

occult neurovesical dysfunction.²⁹ The combination of rec-tourinary fistula and neurovesical dysfunction or bladder outlet obstruction predisposes to critical neonatal illness.

Cases of cloaca should never be managed by initial anorectal reconstruction alone, which necessitates extensive and complicated subsequent surgery. A fully diverting colostomy with complete evacuation of the distal limb should initially be considered. The goals of management in the first few years of life are to protect the upper urinary tract, ensure low-pressure urinary drainage, normalize anorectal anatomy, and minimize any neurologic deficit that may arise from treatable spinal pathology. A comprehensive, integrated approach with posterior sagittal anorectourethrovaginoplasty at approximately 6 to 12 months of age is the most appropriate definitive surgical procedure yielding excellent results in such cases. If bladder outlet obstruction or neurovesical dysfunction is detected or suspected, incidental appendectomy is contraindicated. The goals of management of the preschool and school-aged child with ARMs are to ensure social urinary and fecal continence and to promote self-esteem and self-care.²⁴

CHAPTER 109 ■ CHILDHOOD TUMORS

BARRIE S. RICH AND MICHAEL P. LA QUAGLIA

KEY POINTS

- In childhood, neuroblastoma is the most common extracranial solid tumor, followed in incidence by Wilms tumor; rhabdomyosarcoma is less common than neuroblastoma and Wilms tumor but has a biphasic age distribution, with 40% of cases occurring in the age range 10 to 19 years.
- Patients with neuroblastoma and an increased number of copies of the *MYCN* gene have a much worse prognosis.
- High-risk neuroblastoma remains one of the central problems in pediatric oncology, with overall survival rates less than 30% despite multidisciplinary therapy and the use of multiagent chemotherapy and myeloablative regimens.
- The standard of care for Wilms tumor in the United States is initial surgical resection, with exceptions to this rule only for extensive intracaval tumors that require cardiopulmonary bypass for extraction, obviously unresectable tumors with documented invasion of contiguous structures, and possibly bilateral tumors, especially if it is unclear which side is most heavily involved; all patients with resectable Wilms tumor receive postoperative chemotherapy.
- Clear cell sarcoma of the kidney is a distinct histopathologic and clinical entity from Wilms tumor with an age distribution similar to that observed in Wilms tumor but a markedly worse prognosis; it has been called the *bone-metastasizing renal tumor of childhood*.
- Modern treatment of rhabdomyosarcoma is multidisciplinary and includes multiagent chemotherapy, judicious resection, and radiation therapy; the intensity of therapy should be tailored to the risk of subsequent relapse as a function of tumor, node, or metastasis stage.

The focus of this chapter is malignant solid tumors of infancy, childhood, and adolescence. Fortunately, these conditions are rare, especially compared with major adult solid malignancies. This rarity, however, poses special problems to the cancer researcher. For the clinician studying the effectiveness of a particular drug or surgical technique, fewer patients are available for randomized trials. Similarly, basic scientists analyzing the effect of a particular genetic mutation of a tumor have limited materials at their disposal. The solution to this problem has been the establishment of The Children's Oncology Group (COG) and the Société Internationale Oncologique Pédiatrique (SIOP) in Europe for the clinical and basic scientific study of pediatric malignancies. Despite the progress these groups have made, less than 30% of children with high-risk neuroblastomas survive more than 5 years. Of children with lymphomas and germ cell tumors, 10% to 30% relapse or become resistant to treatment. Approximately 10% of children with hepatocellular carcinomas survive more than 5 years after diagnosis, and almost no patients who have rhabdoid tumor, pediatric colon cancer, or renal cell carcinoma in childhood survive more than 5 years. This has resulted in a 70% increase in the overall survival rate for pediatric cancer over the last 50 years.¹ Overall 5-year survival rates for all stages are approximately 85% for Wilms tumor, 70% for hepatoblastoma, and 60% (83% to 31% by stage, age, and site²) for rhabdomyosarcoma. In comparison, the survival rate was less than 20%, and closer to zero, respectively, for these malignancies before the advent of multidisciplinary therapy.

Future progress will depend on myriad biologic analyses done on each tumor system. As in the past, the pediatric surgical oncologist, the first line of defense in tumor diagnosis and staging, will be instrumental to advances in the field.³⁻⁵ It is crucial that biopsy specimens be adequate both in size and quality. Snap freezing of portions of a tumor biopsy should become routine. Because molecular biologic studies often require a biopsy larger than 1 cm,³ this factor should be kept in mind when planning the operative approach.

INCIDENCE OF SOLID TUMORS IN CHILDHOOD

1 The percent distribution for all races and sexes of various pediatric solid tumors are compared in Figure 109.1.⁶ Neuroblastoma is the most common extracranial solid tumor, followed in incidence by Wilms tumors. Rhabdomyosarcomas account for about three-quarters of the previous two but have a biphasic age distribution, with 40% of cases occurring in the 10- to 19-year-old age range. Hepatoblastomas occur much less frequently, and hepatocellular carcinomas are, fortunately, extremely rare. Many germ cell tumors occur in adolescents or young adults.

FIGURE 109.1. Percentage distribution of common pediatric solid tumors by age group.

NEUROBLASTOMA

Epidemiology and Associated Conditions

Neuroblastoma is the most common extracranial solid tumor and the most common abdominal malignancy of childhood. High-risk neuroblastoma remains one of the central problems of pediatric oncology, with long-term survival less than 40%.^{7,8} Neuroblastoma represents 8% to 10% of cancers diagnosed in children and approximately 15% of cancer deaths in this population.^{9,10} The age-adjusted incidence for patients younger than 15 years is 10.5 per million. The overall male-to-female incidence is 1.2:1, and there is no racial disparity.¹⁰ Neuroblastoma is much more likely to occur in infancy, with a median age of diagnosis at 23 months.¹⁰ Forty percent of tumors are identified in the first year of life, and 75% of tumors are seen by the fourth birthday.¹¹ The overall incidence of neuroblastoma has remained stable over a 21-year period.

Despite overall stable rates, neuroblastoma incidence among infants has increased somewhat during recent years. This increase may be a result of mass screening in certain areas. However, screening does not identify tumors with poor prognosis in older children and does not reduce mortality.¹²⁻¹⁴

Case reports associating neuroblastoma with fetal exposures, such as fetal alcohol syndrome, hydantoin exposure, or phenobarbital exposure, have not been supported by larger studies.^{15,16} The occurrence of neuroblastoma has also been associated with neurofibromatosis type I (NF1), Beckwith-Wiedemann syndrome, Hirschsprung disease, musculoskeletal and cardiovascular malformations, Turner syndrome, and neurodevelopmental abnormalities.¹⁷⁻¹⁹ However, data for these associations remains conflicting. Mutations in PHOX2B gene, which is often associated with congenital central hypoventilation disorder, have been recognized in those with familial neuroblastoma and in 2.3% of those with sporadic neuroblastomas.²⁰ Possible but unproven environmental risk factors include parental exposure to solvents or electromagnetic fields, maternal hormone use during pregnancy, and parental cigarette smoking.²¹

Recently, it was discovered that genetic mutations in the anaplastic lymphoma kinase (ALK) gene explain most hereditary neuroblastomas and also activating mutations can be somatically acquired.²² This has set the scene for the development of therapeutic strategies based on ALK inhibition.²³

Basic Science

2 Neuroblastoma was the first tumor in which molecular biologic advances in the field of oncogenes were translated into a clinically useful tool. The MYCN oncogene (formerly N-myc), was empirically shown to be a useful predictor of survival and risk. Patients with an increased number of copies of the MYCN gene have a much worse prognosis.²⁴ Most authorities consider a copy number of more than 10 to be significant. It has also been shown that when MYCN is amplified in the primary tumor, it is amplified in any metastatic deposits or recurrent tumors. One study demonstrated that MYCN amplification is an independent predictor of outcome in infants with neuroblastoma, although it remains a strongly adverse prognostic indicator in children diagnosed after 12 months of age. This finding is supported by an Italian study that showed that MYCN amplification was an adverse prognostic factor except in patients with stage 4s disease.²⁵ More recent studies, however, have shown that the poor prognostic value is present in 4s disease as well.^{26,27} The MYCN oncogene has been identified in 25% to 35% of diagnosed neuroblastomas; amplification is present in 30% to 40% of stage III and IV neuroblastomas and only 5% of those with localized or 4s disease.¹⁰

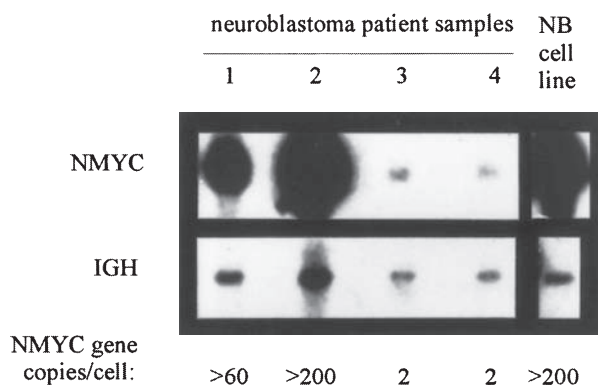

FIGURE 109.2. Example of *MYCN* amplification analysis by Southern blotting in neuroblastoma samples from four patients. The Southern blot hybridization signal obtained with the *MYCN* probe is normalized to that obtained on the same blot with a control probe for a gene not subject to amplification, such as the immunoglobulin heavy chain gene (*IGH*). The signals are then normalized to a negative control (placental DNA, not illustrated). A neuroblastoma cell line with *MYCN* amplification is used as a positive control. The *IGH* signals show that similar amounts of DNA are present in each lane, but the *MYCN* signals are grossly different from each other, indicating amplification in cases 1 and 2 and in the control cell line. Samples 1 and 2 show high-level *MYCN* amplification, exceeding 60 and 200 copies of *MYCN* per cell, respectively, which corresponds to greater than 30-fold and 100-fold amplification. Samples 3 and 4 contain two copies of *MYCN* per cell, as expected in diploid cells without amplification. (Courtesy of Marc Ladanyi, M.D., Department of Pathology, Memorial Sloan-Kettering Cancer Center.)

Rapid assessment of the *MYCN* copy number can be performed using the process of in situ fluorescent hybridization. An example of a tumor analysis from a patient is presented in Figure 109.2. The mechanism of *MYCN* amplification in neuroblastoma remains unknown. *MYCN* is a DNA-binding protein and has been shown to increase the levels of endogenous MDM2 mRNA and protein with consequent p53 inhibition. Modulation of MDM2 levels by *MYCN* may partially explain its role in neuroblastoma resistance to therapy.^{28,29}

The most common cytogenetic abnormalities in neuroblastoma are 1p deletion and a gain of genetic material on 17q.³⁰ The presence of a 1p deletion correlates with a worse outcome in neuroblastoma and has been used as a prognostic factor.^{31–33} It has been shown using cell fusion that replacement of this deleted segment is associated with a marked reduction in tumorigenicity.³⁴ More recently, interest has focused on the unbalanced gain of genetic material on the long arm of chromosome 17. In one multivariate analysis, a gain at 17q was a significant predictor of outcome and was associated with a worse prognosis.³⁵ Likely involved genes on 17q include *NM23* and the *BIRC5* (surviving gene).¹⁰ This factor had a greater impact on outcome than either stage or 1p status. In addition, 11q loss is seen in approximately 35% to 45% of neuroblastoma patients.^{36–38} Deletions of 11q have an inverse relationship with *MYCN* amplification and thus detect a high-risk population as well.¹⁰

Another active area of neuroblastoma research is the relation of nerve growth factor receptors to differentiation and clinical risk. The low-affinity nerve growth factor receptor gene *LNGFR* and the *TRK* proto-oncogene, which is a component of the high-affinity nerve growth factor receptor, are expressed in human neuroblastoma tissue. Several authors have shown that *LNGFR* and *TRK* (*TRK-A*) expression are inversely correlated with *MYCN* amplification and associated with lower stage at diagnosis and improved prognosis.^{39–41} The absence of *TRK-A* expression was highly correlated with *MYCN* amplification in one study, in which 96% of *MYCN*-amplified tumors lacked *TRK-A* expression.⁴² *TRK-C* expres-

sion is also a favorable prognostic factor in neuroblastoma, whereas *TRK-B* expression is associated with poor survival.⁴³ One recent study used microarray analysis to identify targets affected by *TRK* gene expression. In this report, *TRK-A* expression was associated with upregulation of proapoptotic factors and angiogenesis inhibitors. In contrast, *TRK-B* expression correlated with the upregulation of genes involved with invasion and therapy resistance.⁴⁴ Its activation is seen with enhanced proliferation, migration, angiogenesis, and chemotherapy resistance of neuroblastoma cells.⁴⁵

Disturbances of conventional apoptotic pathways are also involved in neuroblastoma, both in spontaneous regression and therapy resistance. The *BCL2* family, survivin, and caspase-8 have all been identified to be involved.^{46–48} In neuroblastoma, Cp-G-island hypermethylation is seen to be the means for functional gene inactivation for caspase-8, TRAIL apoptosis receptors, and the caspase-8 inhibitor, among others.^{47,49} Since gene hypermethylation, therefore, may lead to resistance patterns to therapies, demethylating agents, such as decitabine, are currently being investigated in preclinical studies.¹⁰ Other features associated with resistance patterns seen in neuroblastoma include expression of *MYCN*, *TrkB/BDNF* signaling or loss of p53 expression.^{45,50,51}

Molecular mechanisms have also been studied regarding involvement in local invasiveness and metastases. Metalloproteinases (mainly MMP9), activating matrix-degrading proteolytic enzymes, and molecules regulating tumor cell adhesion and migration, such as CD44 and NM23-H1, have all been identified to be involved.^{52–55}

DNA index of neuroblastoma is also linked to prognosis and responsiveness of therapy. Hyperdiploid DNA content is coupled with a better prognosis and early-stage disease. Alternatively, diploid DNA content is found in approximately 66% of advanced-stage disease and frequently portends resistance to chemotherapy treatment.^{56,57}

Pathology

Neuroblastoma is one of several peripheral neuroblastic tumors (pNTs). Neuroblastoma cells are derived from the primitive neural crest, as are melanocytes; Schwann cells; neuroendocrine or amine precursor uptake and decarboxylation (APUD) cells; and C cells of the thyroid gland, the autonomic nervous system, and the adrenal medulla. Neuroblastoma cells are thought to arise from primitive sympathoblasts functioning as stem cells and sometimes called *I cells*.⁵⁸ Under certain circumstances, these pluripotent cells demonstrate an ability to differentiate along a separate neural crest lineage. For instance, pure ganglioneuroma is thought to arise from complete differentiation of primitive neuroblasts into ganglion cells. Both Schwann cell and melanocytic differentiation are well-reported in these tumors. Finally, because the sympathetic nervous system extends along the entire neuraxis, neuroblastoma can arise from cervical, thoracic, abdominal (retroperitoneal), and pelvic primary sites.

Neuroblastoma is a small, round, blue cell tumor of childhood characterized by sheets of cells staining with hematoxylin. Other tumors that fall into this category include primitive neuroectodermal tumors (PNET) and Ewing sarcoma, non-Hodgkin lymphomas, and undifferentiated sarcomas. Light microscopy can identify Homer-Wright pseudorosettes, ganglion cells, neuropil and neuritic processes, and schwannian stroma (Fig. 109.3). Homer-Wright pseudorosettes, seen in up to 50% of cases, consist of rings of dark-staining neuroblasts surrounding an eosinophilic core of neuropil.⁵⁹ Diagnosis can be aided by immunohistochemical staining that is positive for neurofilament proteins (S-100), synaptophysin, neuron-specific enolase, ganglioside GD2, chromogranin A, and tyrosine hydroxylase (improved diagnosis with negative staining for markers found in other small round cell tumors).⁶⁰ PNETs

FIGURE 109.3. Typical neuroblastoma with monotonous cellular patterns. Note the mitotic figure (*center*) ($\times 450$).

may express neuron-specific enolase but not the other neural markers.⁶¹

At presentation, most neuroblastomas are highly cellular and have a uniform appearance. After chemotherapy, the tumor often appears to have rests of neuroblasts contained in a schwannian stroma. This histologic appearance is called *ganglioneuroblastoma*, and although it appears more differentiated, there is no impact on clinical risk, which is determined by the findings at initial diagnosis. It is also possible for tumors to contain significant amounts of stroma at diagnosis, which is associated with improved outcome. This observation is the basis of the Shimada grading system, which is summarized in Table 109.1.⁶² To help predict risk, all neuroblastomas should undergo Shimada classification at diagnosis.

A new, rare yet aggressive, phenotype of neuroblastoma has been described called large cell neuroblastoma. It is a poorly differentiated schwannian stroma-poor tumor with large cells that have sharply outlined nuclear membranes and one to four prominent nucleoli. It is classified with the undifferentiated and poorly differentiated subtypes.⁶³

TABLE 109.1 CLASSIFICATION

SHIMADA HISTOPATHOLOGIC CLASSIFICATION OF NEUROBLASTOMA

FAVORABLE

Stroma rich, all ages, no nodular pattern
Stroma poor, age 1.5–5 y, MKI <100
C, 1.5 y, MKI, 200

UNFAVORABLE

Stroma rich, all ages, nodular pattern
Stroma poor, age >5 y
Stroma poor, age 1.5–5 y, undifferentiated
Stroma poor, age 1.5–5 y, differentiated, MKI >100
Stroma poor, age > 1y, MKI >200
MKI, mitosis–karyorrhexis index (number of mitoses and karyorrhexis per 5,000 cells).

Neuroblastoma metastasizes to regional lymph nodes and distant sites, most frequently bone marrow and cortical bone. The liver and, rarely, lungs can also be sites of metastatic spread. Cortical bone involvement as manifested by a positive bone scan is a particularly poor prognostic indicator.⁶⁴

Presentation, Workup, and Staging

Clinical presentation depends on site of origin, age at diagnosis, and the biologic aggressiveness of the tumor. The primary site of tumor is not located in 1% of patients.¹⁰ Patients with metastatic or large, bulky tumors, especially if older than 1 year, may appear generally ill or anemic. The proportion of patients with cervical or pelvic tumors is higher in patients younger than 1 year than in older children. Cervical tumors present as a lateral neck mass, yet rarely cause any airway compromise. Because they arise from cervical sympathetic ganglia, cervical tumors may be associated with Horner syndrome, which is often permanent after resection and should be discussed before surgery with the parents. Regional nodal involvement is common, but distant metastases are rare and most tumors are of low risk. Primary thoracic tumors can present with respiratory distress; however, they are often detected on incidental chest radiographs.

Pelvic tumors usually are diagnosed after palpation of a mass. Bladder symptoms, bowel symptoms, and hydronephrosis can occur when pelvic tumors reach great size and compress these organs. Epidural extension to the sacrum can also be noted, and neurologic evaluation documenting somatic motor and sphincter function is mandatory.

The most common presentation among all age groups is an abdominal tumor that is often hard and fixed. The tumor arises from the midline sympathetic nerves or the adrenal gland. Often, regional nodal echelons are involved along the aorta. These involved nodes can be bulky and may extend distally to the aortic bifurcation and proximally into the mediastinum, overshadowing the primary tumor. Invasion of epidural or intradural spaces can occur, and therefore, focal neurologic deficits may be present.

Several syndromes are particularly associated with neuroblastoma: periorbital ecchymoses (racoon eyes), opsoclonus–myoclonus syndrome, and the secretory diarrhea syndrome. Periorbital ecchymoses are caused by orbital metastases with subsequent obstruction and rupture of veins in the periorbital skin (Fig. 109.4). Vision is not usually threatened, and the ecchymoses often take months to resolve even after the orbital tumors have regressed. Opsoclonus–myoclonus, seen in 2% to 4% of patients with neuroblastoma, is a paraneoplastic syndrome thought to be caused by the development of antibodies against the tumor that cross-react with Purkinje cells in the cerebellum. It consists of rapid eye movements, ataxia, and irregular muscle movements.⁶⁵ Unfortunately, the symptoms may not resolve after tumor resection and can therefore result in devastating neurologic injury. Secretory diarrhea syndrome is caused by release of vasoactive intestinal peptide by the tumor. The watery diarrhea may require intravenous support but usually resolves with treatment and resection of the tumor.⁶⁶ This condition is an indication of tumor differentiation and is associated with low-risk lesions.

The workup is directed toward delineation of tumor extent in the primary site and identification of metastatic deposits. The primary site is usually evaluated by computed tomography (CT) or magnetic resonance imaging (MRI). CT is effective for characterizing the primary tumor site and its lymphatic extension. The lower chest should be included in scans of cervical primaries; the upper abdomen and lower neck in thoracic tumors; and the entire abdomen, pelvis, and lower chest for abdominal primaries. CT of the skull can detect widespread disease. Recently, MRI has been shown to be superior to CT for staging of neuroblastoma, as it demonstrates bone marrow and cortical

FIGURE 109.4. Periorbital neuroblastoma. (From Fleisher GR, Ludwig W, Baskin MN. *Atlas of Pediatric Emergency Medicine*. Philadelphia: Lippincott Williams & Wilkins; 2004, with permission.)

bone involvement, better characterization of intrahepatic lesions, and intraspinal extension.⁶⁶ When CT scans are used, they should be performed with both gastrointestinal and intravenous contrast. This is true even for cervical and thoracic primaries so that the position and course of the pharynx and esophagus are precisely determined. If CT or MRI scans include the liver, appropriate windows can be used to identify hepatic metastases. Ultrasound can also be used in this regard, and plain chest films are used to identify pulmonary metastases. If pulmonary metastases are present, Doppler ultrasonography can be used to identify intracaval tumor extension. It is also useful to perform a ⁶⁷I (or ⁶⁸I) metaiodobenzylguanidine scan to assess metastatic sites and as a baseline for evaluation of therapeutic response in the primary site.⁶⁸ I scans are more sensitive and preferable for imaging. About 10% of neuroblastomas do not

take up metaiodobenzylguanidine (MIBG) and a useful surrogate is a positron emission tomography (PET) scan.⁶⁹ One study on MIBG use for diagnosis of neuroblastoma showed that using scintigraphy with CT significantly increased the detection of stage 4 disease.⁷⁰ Likewise, MIBG has been shown to locate bone marrow or cortical bone disease not otherwise found.⁷¹ However, because of the high incidence of cortical bone involvement, especially in children older than 1 year, bone scans are performed routinely. The bone marrow is assessed by bone marrow aspiration at four iliac crest sites and bone biopsy at two sites. Finally, a 24-hour urine collection for measurement of metanephrine, dopamine, and vanillylmandelic acid may help diagnostically and as a tumor marker to assess therapeutic response. Diagnosis of neuroblastoma requires histologic confirmation either by direct tumor biopsy or by demonstration of malignant cells in bone marrow samples. Because of the wide range of molecular biologic studies that have prognostic importance, many groups attempt to obtain enough tissue at diagnosis to allow full molecular biologic and cytogenetic analysis in addition to histologic diagnosis. When possible, several grams of tumor tissue should be obtained, and a portion should be snap frozen. Biopsy can usually be achieved through a minilaparotomy or laparoscopic approach. Some groups have questioned the ethics of open biopsy when diagnosis can be obtained by examination of the bone marrow and assessment of urinary catecholamines. Some groups have tried to avoid initial minilaparotomy and base the diagnosis on elevation of urinary catecholamines and bone marrow aspirates. In this situation, biologic studies are dependent on the number of tumor cells in the aspirate with MYCN copy number assessed by fluorescent in situ hybridization.

The most widely used staging system for neuroblastoma is based on the international system, which is listed in Table 109.2.⁷²⁻⁷⁴ This system evolved from previous systems developed by Evans et al. and the Pediatric Oncology Group (POG).⁷⁵ Tumor size and location relative to the midline remain important determinants of stage, as does the presence and degree of metastatic disease. The present system is also highly dependent on surgical resection of the primary tumor in patients with nonmetastatic disease. Recently, the International Neuroblastoma Risk Group developed a staging system based on tumor imaging and bone marrow morphology, rather than surgical resection, for pretreatment risk assessment, which is listed in Table 109.3.⁷⁶ This was developed to be used concurrently with the international system. The midline is not

incorporated into this assessment.⁷⁶ Prospective analyses to validate this new system are ongoing.

Risk Groups

Neuroblastoma patients are categorized into high-, intermediate-, and low-risk groups at diagnosis. This assessment is based on age, stage, Shimada classification, and the results of specialized studies, including flow cytometry, analysis for MYCN amplification, cytogenetics, and TRK gene expression. Ancillary criteria include serum ferritin, lactate dehydrogenase, and neuron-specific enolase determinations at diagnosis and before blood transfusion. Table 109.4 lists criteria for the risk

groups.¹⁰ Risk assignment is important because it strongly determines therapy. Although 1 year was previously the cutoff age to differentiate between low and high risk, recent studies have demonstrated that diagnosis before 18 months improves prognosis. Investigations with less aggressive treatments are ongoing regarding the treatment of children ages 12 to 18 months with locoregional or metastatic disease.¹⁰

Treatment

Neuroblastoma treatment depends on degree of risk, as noted earlier. In general, low-risk tumors do not require chemotherapy or radiation. Resection of the primary lesion to obtain the

diagnosis and biologic markers is followed by observation. Serial imaging studies of the primary and possible metastatic sites in low-risk patients are performed. Urinary catecholamines should fall to normal levels and remain there. Chemotherapy is an option for those with low-risk neuroblastoma as a salvage therapy only for those who relapse after surgery.^{77,78} Since those with Stage 4s without MYCN amplification often have spontaneous regression of disease, chemotherapy or low-dose radiotherapy is used only in those patients who are symptomatic from tumor burden, including substantial hepatomegaly leading to bowel obstructions or respiratory distress.^{79,80}

Intermediate-risk neuroblastoma is treated with both surgical resection and moderate-dose, multiagent chemotherapy, which includes cisplatin/carboplatin, doxorubicin, etoposide, and cyclophosphamide.¹⁰ For those whose tumor has favorable histology, survival is often greater than 95%.⁸¹ Studies are ongoing in the hopes of minimizing treatment regimens for this group of patients.

3 High-risk neuroblastoma remains one of the central problems in pediatric oncology, with overall survival rates less than 30% despite multidisciplinary therapy and the use of multiagent chemotherapy and myeloablative regimens. Standard therapy for patients with high-risk neuroblastoma involves induction chemotherapy, local control with aggressive surgical resection and external-beam radiotherapy, consolidation therapy, and treatment of minimal disease with biologic agents. Local control is completed despite a response to induction therapy.¹⁰

Initial surgery should be confined to acquisition of diagnostic tissue, staging, and placement of a vascular access device. Surgical complications are higher after initial attempts at complete resection without impact on survival.⁸² After a course of chemotherapy, usually four or five cycles, second-look surgery is performed (Fig. 109.5). Although perspectives on resection in high-risk patients vary, most authorities agree that complete gross resection, which is associated with excellent local control, should be the goal of second-look procedures.⁸³ The approach is dictated by the particular properties of the primary tumor. For upper abdominal lesions, especially those involving major midline branches of the abdominal aorta or the vena cava, thoracoabdominal exposure is helpful and well tolerated. The goal of resection is a complete vascular dissection and should encompass not only the primary but also all involved regional nodal echelons.

Chemotherapy for neuroblastoma has evolved toward higher dose intensities of multiple agents. In one meta-analysis, increased dose intensity correlated with improved overall and disease-free survival rates. In another report, primary tumor resectability correlated with increased chemotherapy intensity. There is no widely accepted regimen, and the major cooperative groups as well as larger single institutions have differing protocols. Standard induction regimens include a combination of anthracyclines, alkylators, platinum compounds, and topoisomerase II inhibitors. The COG is considering topotecan as an agent during induction. During induction therapy, stem cells are harvested and allocated for later use in the consolidation phase of treatment.⁹

Local control is achieved after induction therapy with a combination of surgery and external-beam radiotherapy. Neuroblastoma is one of the most radiosensitive solid tumors in pediatric oncology.⁸⁴ Doses of 2,160 cGy are given daily in 180 cGy fractions to the primary site of tumor. Risk of local recurrence is higher if residual tumor remains after induction therapy. Current studies are investigating higher doses of external-beam radiation for improved local control.

After induction and local control with second-look resection, patients will receive consolidation therapy with a high-dose chemotherapy and hematopoietic stem cell transplant. Chemotherapeutic agents used for consolidation include carboplatin, etoposide, and melphalan.⁸⁵ Studies looking at high-dose chemotherapy with stem cell rescue compared to maintenance chemotherapy alone have shown improved event-free survival.^{7,86} Survival has been improved further with the use of

FIGURE 109.5. A: Initial computed tomography (CT) scan of a child with stage 4 neuroblastoma. B: CT scan of the same child after incisional biopsy and cytoreductive chemotherapy. Residual tumor is present despite dramatic reduction in overall tumor size.

purged, peripheral blood hematopoietic stem cells.⁸⁷ Early studies have shown increased event-free survival with rapid sequential tandem transplant consolidation therapy, which has spurred the ongoing phase III COG trial testing single versus tandem transplant as consolidation therapy.⁸⁷ The CCG-3891 study indicated that treatment with 13-*cis*-retinoic acid after bone marrow transplantation was associated with an improved survival rate.⁷ Recently, investigators from the COG have observed, in phase III trials, improvements in overall survival and event-free survival with *cis*-retinoic acid plus a three-part immunotherapy: chimeric anti GD-2 antibody ch14.18, interleukin-2 (IL-2), and granulocyte-macrophage colony-stimulating factor (GM-CSF) for patients with high-risk neuroblastoma, after induction with dose intensive chemotherapy.⁸⁸ Chimeric anti GD-2 antibodies recognize the surface ganglioside GD2 that is usually highly expressed on the surface of human neuroblastoma cells. Further trials for this regimen are in progress.

Future Directions

Even with aggressive treatment, less than 30% of those diagnosed will survive.^{89,90} Therefore, new methods for treatment continue to be studied. As neuroblastoma is typically a radiosensitive tumor,⁶⁷ IMiBG infusion signifies a way to specifically deliver radiotherapy to malignant cells. The COG is planning a pilot trial to evaluate the efficacy of MIBG with high-dose chemotherapy regimens. Bisphosphonates are under investigation as a possible agent to delay bone metastases. Nifurtimox, an antiparasitic agent, has shown some cytotoxic

effects against neuroblastoma cell lines, and a phase I study is currently in progress. Rapamycin (an immunosuppressive drug also known as sirolimus) affects a pathway that is important for the cell growth and continued existence of neuroblastoma tumors through interactions with mTOR (mammalian target of rapamycin). Phase II trials including mTOR inhibitors are ongoing. Preliminary studies demonstrated a benefit to those with recurrent neuroblastoma.⁹¹ Further studies are investigating the AKT pathway, as activation of AKT correlates with worse event-free and overall survival; however, no specific inhibitors are clinically available at this time.^{92–94} Tumor vaccines and techniques of adoptive immunotherapy are being evaluated in clinical trials but so far are not curative. Biologic agents, such as histone deacetylase inhibitors, Trk tyrosine kinase inhibitors, MYCN inhibitors, and anaplastic lymphoma kinase (ALK) inhibitors, and various antiangiogenic agents have been proposed for use in minimal disease states and are undergoing clinical trials. In intermediate-risk neuroblastoma, there is a strong trend to eliminate or minimize chemotherapy.

WILMS TUMOR

Epidemiology and Associated Conditions

Malignancies of the kidney represent 6.3% of all cancer diagnoses among children younger than 15 years, with an incidence

of 7.9 per million.⁹⁵ In the United States each year, approximately 550 children younger than 20 years are diagnosed with a renal cancer, 500 of which are Wilms tumors. The overall incidence of Wilms tumor or nephroblastoma is 8 per 1 million children younger than 15 years.⁹⁶ The incidence is highest among African Americans and lowest among patients of East Asian descent. The sex ratio is approximately 1:1, and the peak incidence occurs between 2 and 3 years.⁹⁷ Most Wilms tumors occur in patients younger than 5 years. Median ages reported from the National Wilms Tumor Study (NWTs) were 36 months for boys and 43 months for girls with unilateral disease, whereas boys and girls with bilateral disease presented at median ages of 23 and 30 months, respectively.⁹⁸ Rhabdoid tumors of the kidney, clear cell sarcomas, and renal cell carcinomas make up 1.0%, 1.6%, and 2.6%, respectively, of renal cancers occurring in children younger than 15 years.⁹⁵ Wilms tumors can arise from areas other than the kidney, but this is extremely rare. The most common extrarenal site is the retroperitoneum, followed by the pelvis and inguinal canal. Stage for stage, extrarenal Wilms tumors have a prognosis similar to that of renal primary tumors and therapy should be guided by principles developed by NWTs.^{99–101}

Table 109.5 lists conditions associated with development of Wilms tumor along with the associated increase in relative risk. In general, the presence of any of these conditions or syndromes should initiate a workup to rule out the presence of Wilms tumor. Known risk factors include race, aniridia,

TABLE 109.5

SYNDROMES ASSOCIATED WITH INCREASED SUSCEPTIBILITY TO WILMS TUMOR^a

■ SYNDROME	■ LOCUS/GENE	■ PHENOTYPE
WAGR (Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation)	11p13/ <i>WT1</i> : large deletions (also involving <i>PAX6</i>)	Absence of the iris (aniridia), genitourinary defects, and mental retardation; 30% of patients develop Wilms tumors
Denys-Drash	11p13/ <i>WT1</i> : point mutations (in the zinc-finger domain)	Genitourinary defects, renal mesangial sclerosis and intersex disorder; 90% of patients develop Wilms tumors
Frasier	11p13/ <i>WT1</i> : point mutations (in the KTS donor splice site)	Genitourinary defects, focal glomerular sclerosis, and intersex disorder; patients rarely develop Wilms tumor
Beckwith-Wiedemann	11p15/Several genes implicated (<i>IGF2</i> , <i>H19</i> , <i>p57</i> , and <i>LIT1</i>)	Abnormally enlarged organs (organomegaly) including the tongue (macroglossia), overgrowth of one side of the body (hemihypertrophy), hypoglycemia, umbilical hernia, and increased risk of several tumors (including Wilms tumor, hepatoblastoma, and adrenal carcinoma); 5% of patients develop Wilms tumors
Simpson-Golabi-Behmel	Xq26/ <i>GPC3</i> : point mutations, microdeletions	Organomegaly, renal dysplasia, excess digits (polydactyly), diaphragmatic and heart defects; 7.5% of patients develop Wilms tumors
Sotos	5q35/ <i>NSD1</i> : point mutations, microdeletions	Overgrowth, craniofacial dysmorphism, mental retardation, and increased risk of several tumors (including Wilms tumor, neuroblastoma, and acute lymphocytic leukemia); 5% of patients develop Wilms tumor
Perlman	Unknown	An abnormally large body (macrosomia), enlarged viscera (visceromegaly), undescended testes (cryptorchidism), excess amniotic fluid (polyhydramnios), characteristic facial features; 30% of patients develop Wilms tumors
Familial Wilms tumor 1 (FTW1)	17q12–21	20% of patients develop Wilms tumors
Familial Wilms tumor 2 (FWT2)	19q13.4	70% of patients develop Wilms tumors

^aSeveral syndromes are associated with an increased incidence of Wilms tumor. There is a wide variation in the risk of Wilms tumor among these conditions. Other syndromes that have also been reported to have an increased incidence of Wilms tumor include neurofibromatosis type 1 and the Li-Fraumeni, hyperparathyroid-jaw tumor, and Bloom syndromes.

genitourinary anomalies, WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, mental retardation), Beckwith-Wiedemann syndrome, Perlman syndrome, Denys-Drash syndrome, and Simpson-Golabi-Behmel syndrome.⁹⁵

Basic Science

For Wilms tumor, cytogenetic abnormalities have been identified on chromosomes 11p13, 1p, and 16q.^{102–104} *WT1*, a gene responsible for genitourinary development, is expressed in the kidney, gonads, spleen, and mesothelium. It was cloned from 11p13 to encode four zinc finger transcriptional factors that have regulatory functions on cell growth, differentiation, and apoptosis.¹⁰⁵ Reduced *WT1* has been linked to stromal predominant Wilms tumor,¹⁰⁶ and lack of *WT1* expression has been seen in WAGR and Denys-Drash syndromes.^{107,108} Only a small percentage of those with sporadic Wilms tumors are found to have mutations of *WT1*.⁵⁶ *WT2* gene, located on 11p15, has been shown to be related to insulin-like growth factor 2, and has been associated with Beckwith-Wiedemann syndrome.^{105,109} In one study, *WTX*, which is located on the X chromosome, was present in 29% of patients with Wilms tumor.¹¹⁰ *WTX* has been shown to be a tumor suppressor gene that controls WNT/beta-catenin signal transduction.¹¹¹ Mutations in H19, beta-catenin, and p57^{Kip2} have been observed in Wilms tumor patients as well. Another study found the p53 tumor suppressor gene in 75% of patients with anaplastic histology.¹¹² *FWT1* (17q) and *FWT2* (19q) have been associated with several familial Wilms tumors.¹¹³ The NWT5-5 trial reported that loss of heterozygosity at chromosomes 1p and 16q is associated with unfavorable outcomes.¹¹⁴ In addition, abnormal E2F3 expression is often seen in Wilms tumors but not other renal tumors. Furthermore, miRNAs (such as miR-17–92 and oncomiR-1) have been shown to be upregulated in Wilms tumors. Since oncomiR-1 is a transcriptional target of E2F3, it has been suggested that this pathway may be involved in tumorigenesis.^{115,116}

Pathology

It is hypothesized that Wilms tumor arises from primitive metanephric blastema. Individual tumors often contain primitive metanephric cells but also cartilage, skeletal muscle, and squamous epithelium. Most tumors arise unifocally within the kidney, but approximately 7% of unilateral Wilms tumors are multicentric.⁹⁷ The proportion of synchronous bilateral tumors among all patients with nephroblastoma ranges from 4.4% to 7%, whereas that of metachronous tumors is 1.0% to 1.9%.¹¹⁷ Wilms tumors have equally distributed laterality and may occur with no apparent connection to the kidneys. Usually, extrarenal Wilms tumor occurs in the retroperitoneal area, but other reported sites include the pelvis, scrotum, and inguinal region.

Grossly, the tumors are globular or spherical and uniformly pale gray or tan on sectioning. Calcification is not usually apparent, unlike the stippled calcifications seen in neuroblastoma; Wilms tumors may have “eggshell” calcification in tumors that have undergone significant spontaneous hemorrhage. Cysts may be present, and in infants, polypoid extension into the pelvicalyceal system may cause confusion with botryoid rhabdomyosarcoma. Also, a pseudocapsule of compressed renal parenchyma is often found. Most tumors, unless composed of a large proportion of stromal elements, are friable and easily ruptured. This is of great significance to the operating surgeon, who must recognize preoperative rupture and avoid intraoperative spillage. The consequence of either of these events is upstaging of the lesion and the need for whole-abdomen radiation therapy with its attendant morbidity.

Microscopically, these tumors demonstrate a triphasic pattern of blastemic, stromal, and epithelial cells. Biphasic tumors

FIGURE 109.6. Wilms tumor (nephroblastoma). This photomicrograph of the tumor shows highly cellular areas composed of undifferentiated blastema, loose stroma containing undifferentiated mesenchymal cells, and immature tubules. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1999, with permission.)

with blastemic and stromal cells are common, and some specimens consist of only a single type (Fig. 109.6). The diffuse blastemal type, although often seen in patients who present with advanced-stage tumors, responds well to chemotherapy.⁵⁶ Tumors with mainly epithelial differentiation are typically less aggressive.¹¹⁸

A major parameter predictive of tumor aggressiveness and patient survival is the histologic finding of anaplasia, defined by the presence of hyperdiploid mitotic figures, threefold or greater nuclear enlargement, and hyperchromasia of enlarged nuclei. The effect of anaplasia on prognosis is so marked that tumors with these findings are designated “unfavorable histology” by the NWT5. Anaplastic tumors, which compose approximately 5% of all Wilms tumors, are rare in the first 2 years of life, but their incidence increases to 13% of patients with a Wilms diagnosis at 5 years or older. These tumors are often resistant to chemotherapy.⁵⁶

Nephrogenic rests are persistent metanephric tissue in the kidney after 36 weeks’ gestation. They have been deemed precursors of Wilms tumor, as they are seen in 30% to 40% of resected kidneys with Wilms. The NWT5-4 study documented that nephrogenic rests were present in approximately half of the unilateral and most of the bilateral tumors.¹¹⁹ Rests can involute, remain quiescent, go through hyperplastic changes, or advance to focal neoplastic lesions.^{56,119} Controversy remains over how to treat incidentally found nephrogenic rests.

Presentation, Workup, and Staging

Most Wilms tumors are first diagnosed after appreciation of an asymptomatic abdominal mass, which can be very large. The mass is usually discovered during routine pediatric examination or while the children are handled by a relative. Parents may need reassurance, as they are usually surprised and feel guilty that such a mass could have gone unnoticed. In a subset of patients, rapid abdominal enlargement develops, associated with pain, fever, and gross hematuria. This is attributed to intratumoral hemorrhage and may be associated with spontaneous rupture. Rarely, patients can present with symptoms of a paraneoplastic syndrome that include hypertension, hypercalcemia, erythrocytosis, and von Willebrand disease.^{120,121}

The NWT5 recommends the following workup for patients with suspected nephroblastoma. An excretory urogram is obtained to identify the tumor site; pelvicalyceal distortion is demonstrated, thus localizing the process to the kidney; and the function of the contralateral kidney is assessed. It is acceptable

FIGURE 109.7. Initial computed tomography scan of a child with a left-sided Wilms tumor. The distortion of the calyceal system is characteristic of intrinsic renal tumor. A kidney (asterisk) is identifiable.

to substitute CT scanning of the abdomen with intravenous and oral contrast for excretory urography (Fig. 109.7). Indeed, almost every center performs this study routinely. Abdominal, real-time Doppler ultrasonography is performed to identify intracaval tumor extension, liver metastases, or enlarged retroperitoneal lymph nodes. Finally, good posteroanterior and oblique plain films of the chest are obtained to identify pulmonary metastases. All data in the NWTs studies concerning stage IV patients are based on a diagnosis made using plain chest radiographs. Several studies support the validity of this approach. In particular, patients with pulmonary metastases diagnosed by CT but not by plain chest films did as well as patients with nonmetastatic disease when staged and treated on the basis of their abdominal tumor alone. Some recommend that patients with pulmonary nodules identified by CT scan, but not plain chest radiographs, undergo biopsy to verify the diagnosis.¹²² Because this recommendation has obvious cost-of-care and quality-of-life implications, some effort to resolve this controversy is needed, given the prevalence of CT scanning.

In the United States, this initial workup is followed by surgical resection of the tumor if possible (Fig. 109.8), which allows surgical and histologic parameters to be included in staging. The surgeon must pay strict attention to the local tumor extent or tumor rupture and status of the regional periaortic, interaortocaval, paracaval, and perirenal lymph nodes. Previously, direct visualization and manual palpation of the contralateral kidney was considered mandatory in all cases, even when CT scans did not indicate involvement. *Surgeons should be aware that the Renal Tumor Committee of the COG no longer recommends this approach.* Finally, the liver should be carefully palpated and the peritoneal and diaphragmatic surfaces inspected for metastases. Recently, initial treatment with chemotherapy has been recommended in cases of bilateral Wilms tumor in patients who have significant vascular invasion (discussed later in this chapter).

Once the imaging and surgical and pathologic data are acquired, a tumor stage is assigned based on the current NWTs staging schema (see Table 109.6).

Treatment

With modern treatment protocols, overall survival rates approximate 90%.¹¹⁸ The focus remains on optimizing tumor response for a cure, while reducing side effects from treatment. **4** The standard of care in the United States is initial surgical resection. Exceptions to this rule include extensive intracaval tumors that require cardiopulmonary bypass for extraction, obviously unresectable tumors with documented invasion of contiguous structures, and possibly bilateral tumors, especially if it is unclear which side is most heavily involved. The European (SIOP) approach is neoadjuvant chemotherapy, and the overall survival is comparable to that found in the United States. For most patients, exploration and resection should be performed through a wide transverse incision that allows comfortable inspection and palpation of the contralateral kidney. As noted earlier, complete sampling of regional nodal echelons is mandatory, as is careful assessment of the tumor margins and possible areas of metastases. Lack of lymph nodes in the surgical specimen confers treatment as stage III disease.¹¹⁸ Although most authors recommend early ligation of the renal vein, most surgeons admit to not perform this maneuver because it is often difficult or unsafe owing to the size of the tumor. The available

FIGURE 109.8. Operative approach to resection of a right renal Wilms tumor.

TABLE 109.6

STAGING

STAGING CRITERIA FOR WILMS TUMOR

■ WILMS TUMOR STAGING SYSTEM ^a		■ FOUR-YEAR SURVIVAL RATE (%)
Stage 1	Tumor limited to kidney and completely excised; surface intact with no evidence of rupture	97
Stage 2	Tumor extends beyond kidney but completely excised; infiltration through the renal capsule, or extension into vessels outside the kidney substance, or local open biopsy or spillage confined to the flank; no residual tumor	95
Stage 3	Residual nonhematogenous tumor	91
Stage 4	Hematogenous metastases to lung, liver, bone, brain, etc.	78
Stage 5	Bilateral renal involvement at diagnosis	Same as for highest-stage unilateral

^aSurvival based on outcome for patients with favorable histologic types in the National Wilms Tumor Study-3. Courtesy of the National Wilms Tumor Study.

data indicate that later ligation of the renal vein after tumor mobilization does not adversely affect prognosis. After the kidney and accompanying Gerota fascia is mobilized, the renal artery is most easily identified by posterior dissection. Radical ureterectomy does not affect outcome, but the ureter should be divided well distal to the calyceal system to ensure any polypoid pelvicalyceal extensions are encompassed. It is essential to perform *en bloc* resection without tumor spillage as this produces a sixfold increase in local abdominal recurrence.¹¹⁸

Nephron-sparing surgery (NSS) is considered for patients with a solitary kidney in addition to those with bilateral Wilms tumor. NSS in those children with unilateral Wilms tumor is controversial. The size of most of the tumor contradicts this method as it would be impossible to obtain negative margins. However, tumors that may allow for the use of NSS include those that involve a single pole of the kidney, if the collecting system and vessels are not involved with the tumor, if there are clear margins between the tumor and adjacent structures, and if the tumor-bearing kidney is adequately functional.¹²³ Laparoscopic resection of renal tumors in children was examined; however, the risks of tumor spillage and inaccurate staging in those without chemotherapy pretreatment hinder this method.¹²⁴ Complications involved with surgical resection of Wilms include bleeding, bowel obstruction, and chylous leak.

All patients with resectable Wilms tumor receive postoperative chemotherapy. A major effort by the NWTTS was the development of chemotherapy protocols for Wilms tumor that minimize toxicity while maintaining efficacy. These studies have shown survival improvements among patients with stage I or II favorable histology disease who undergo combination chemotherapy with vincristine and actinomycin D. The current 4-year relapse-free and overall survival for favorable histology stage I Wilms tumors are 94% and 98%, respectively, and relapse-free and overall 4-year survival for favorable histology stage II Wilms tumors are 85% and 96%, respectively. Recommended treatment is initial nephrectomy and lymph node sampling followed by 18 weeks of vincristine and dactinomycin chemotherapy. For stage I patients with focal or diffuse anaplasia, a similar regimen is used, and the 2-year relapse-free and overall survival is about 86%. Stage II patients with focal anaplasia receive vincristine, dactinomycin, and doxorubicin for 24 weeks as well as abdominal radiation. Stage II patients with diffuse anaplasia are treated with vincristine, cyclophosphamide, doxorubicin, etoposide, and mesna for 24 weeks and also receive abdominal radiation. Four-year survival is 70% in this group.^{68,125} Favorable histology stage III tumors or those with focal anaplasia are treated with nephrectomy, lymph node sampling, 24 weeks of vincristine, doxorubicin, and pulse-intensive dactinomycin and abdominal radiation.⁶⁸ This regi-

men results in a 90% 4-year relapse-free survival and 95% 4-year overall survival. For stage III patients with diffuse anaplasia, nephrectomy, lymph node sampling, abdominal radiation, and 24 weeks of vincristine, doxorubicin, cyclophosphamide, and etoposide are given, resulting in a 56% 4-year survival.¹²⁶

Patients with stage III favorable histology disease generally undergo external beam radiation therapy. The usual dose is 1,000 cGy. The entire kidney bed and areas of gross residual disease are targeted and radiation delivered to the entire vertebral column at the level of involvement to minimize the risk of scoliosis. Patients with stage IV disease should have their primary tumor staged as if metastases were not present. If the primary kidney tumor is stage I or II, no local radiation is delivered; the previously noted guidelines are followed for primary stage III tumors. Pulmonary metastases, nonresectable liver metastases, bulky nodal brain metastases, and skeletal metastases are treated with external-beam radiation therapy. The COG is currently undergoing trials regarding both radiation treatment and chemotherapy to further improve risk-stratified therapies for Wilms tumor.

Bilateral Wilms Tumor

Of patients diagnosed with Wilms tumor, approximately 4% to 7% of them will have simultaneous bilateral tumors. The overall survival rate of patients with bilateral Wilms tumor is 87%.¹²⁷ The survival rate for this disease is high because 90% of cases are of favorable histology, and most kidneys are stage I when considered individually. Because of the danger of debilitating loss of renal function, it is acceptable to administer preoperative chemotherapy. Renal biopsy in obvious cases of bilateral involvement based on imaging studies is not necessary. After tumor shrinkage, nephron-sparing renal resection can be performed. Survival rates using this strategy are equivalent to those using the more traditional approach. The latter involves an initial nephrectomy of the most heavily involved kidney, followed by chemotherapy and then re-exploration.¹²⁸ For patients whose disease progresses or does not respond to chemotherapy (with or without radiation), biopsies should be obtained to identify histology for further management planning. Specifically, those with anaplastic tumors should be identified for early resection and intense postoperative chemotherapy.¹²⁹ Furthermore, patients with bilateral tumors who obtain complete radiographic resolution after initial therapy (without surgery) have minimal risk of local recurrence and can be monitored by serial imaging.¹³⁰

Renal Vein and Inferior Vena Cava Involvement

A study from NWTs-3 included 164 patients with gross involvement and 47 patients with microscopic involvement of the renal vein beyond the kidney (11.3%). Two-year survival rates for patients with stages I, II, and III disease were 90%, 79%, and 72%, respectively. Important predictors of outcome were histologic pattern and stage. The authors suggested that complete *en bloc* resection of the primary tumor and the renal vein extension constituted the most effective initial management.¹³¹ In a second report from the NWTs, 165 of 2,731 Wilms tumor patients had intravascular extension (6%).⁶⁷ Vascular extension involved the inferior vena cava in 134 cases and the atrium in 31. Of these, 69 patients received preoperative neoadjuvant chemotherapy for a median of 8 weeks; 55 were treated for caval extension and 14 for atrial extension. The intravascular extension regressed in 39 of 49 patients. The overall complication rate was not statistically different in patients undergoing neoadjuvant chemotherapy compared with those treated with immediate surgery and occurred in 36.7% of patients with atrial extension compared with 17.2% of those with tumors localized to the inferior vena cava. The authors suggest that neoadjuvant chemotherapy be used in most patients with vascular extension.

Three-year relapse-free survival rates of patients with intravascular tumor extension (76.9%) do not statistically differ from the overall Wilms tumor rates (80.3%).⁶⁷ It has been suggested that a complicated operation involving cardiopulmonary bypass can be safely avoided by administration of preoperative chemotherapy. A second-look procedure should then be performed and all residual tumors resected. Second-look surgery is usually less complicated, and resection can be accomplished using conventional means. Tumor shrinkage usually is rapid when cytotoxic drugs are first administered but stabilizes after four to five cycles of therapy. At this point, no further tumor reduction can be expected and resection should be planned with appropriate preoperative consultation from other services (e.g., cardiovascular) as indicated. Nevertheless, a preoperative workup that includes Doppler ultrasonography should always be performed before operation. Contrast vena cavography has become less critical with advances in contrast-enhanced CT or MRI techniques, which now provide detailed information concerning the vascular anatomy. Nevertheless, the anatomic extent of the tumor thrombus must be determined before surgery. If tumor thrombus continues to extend to the proximal vena cava or right atrium, resection should be coordinated and performed under cardiopulmonary bypass. Without resection, intraoperative tumor embolism, which is often fatal, may be the result.

Adult and Neonatal Wilms Tumor

Wilms tumors that occur at both ends of the age spectrum are rare.^{132,133} In a recent review from 1960 to 2007 including 47 fetuses and 163 infants with renal tumors, 139 had congenital mesoblastic nephromas, 41 had Wilms tumors, 23 rhabdoid tumors, and 7 clear cell sarcomas. Of those with Wilms tumor, 65.9% were stage I, none were stage IV, and 12.2% were bilateral.¹³⁴ Fetal and neonatal Wilms is treated with initial surgery, which is often curative.¹³⁴ Chemotherapy is used for those with stage IV disease or inoperable tumors.^{135–137} When chemotherapy is used in children less than 1 year of age and stage greater than II, a 50% reduction in the dose of chemotherapy is recommended.^{135,137} Adult Wilms tumors are associated with worse outcomes, even in patients with favorable histology. A 3-year overall survival rate reported by NWTs supports the use of aggressive therapy in all adult patients with Wilms tumor.^{138–140}

Future Directions

Future work will focus on individualizing treatment to patients based on risk stratifications and minimizing side effects. As loss of heterozygosity (LOH) of 1p and 16q has worse outcomes, current COG studies are looking into more intensive treatment for this subset of patients. Other areas of investigation include the role of autologous bone marrow transplantation in patients with relapsed favorable and unfavorable histology disease, and attempts to improve outcome in the non-Wilms renal tumors in childhood. In this regard, sarcoma-like protocols, using agents such as cisplatin, ifosfamide, and etoposide, are being evaluated.

NON-WILMS RENAL TUMORS OF CHILDHOOD AND ADOLESCENCE

Clear Cell Sarcoma

- 5 Clear cell sarcoma of the kidney is considered a distinct histopathologic and clinical entity from Wilms tumor.¹⁴¹ It has an age distribution similar to that observed in Wilms tumor but a markedly worse prognosis. Male-to-female ratio is 2:1. This tumor is characterized by a proclivity to metastasize to bones and has been called the *bone-metastasizing renal tumor of childhood* by British workers. Grossly, the tumors are soft, tan-grey, and well-demarcated. Histopathologically, the tumor consists of cords and nests of pale-stained tumor cells separated by vascular structures. Confusion with classic Wilms tumor is possible, however, and central pathologic review is recommended. Clear cell sarcoma can metastasize not only to bone but also to brain. Bony metastases are usually polyostotic, but the skull is almost invariably involved. A CT scan of the abdomen or intravenous urogram, chest radiograph, MRI of the brain, and bone scan are recommended as part of the workup. The staging system is similar to that for Wilms tumor, but high rates of tumor relapse are associated with even stage I tumors, supporting the use of aggressive systemic chemotherapy in all stages. Relapse and death occur in 75% of patients treated with actinomycin-D and vincristine alone, with more than half dying within 1 year of diagnosis. The addition of doxorubicin to the treatment regimen for these children has resulted in significant survival improvement with a 6-year relapse-free survival of 64.6%.¹⁴² Treatment recommendations include radical resection of the primary tumor when possible as well as involved regional lymph nodes, followed by a postoperative chemotherapy regimen that includes doxorubicin, actinomycin D, and vincristine. In one randomization, a 15-month course of chemotherapy compared with 6 months improved relapse-free survival but not overall survival.¹⁴³ Preliminary results of NWTs-5 patients treated with 6 months of vincristine, doxorubicin, and actinomycin D alternating with cyclophosphamide/etoposide with radiotherapy report a 5-year event-free survival of 79% and an overall survival of 89%.¹⁴⁴ Postoperative radiation therapy to the tumor bed is recommended regardless of stage. Usually, 1,080 cGy of postoperative flank irradiation is administered. Patients should be followed with serial chest radiographs or CT scans and 6-monthly brain MRI scans and bone scans for at least 3 years after treatment.

Rhabdoid Tumor

Rhabdoid tumors are rare malignancies that most commonly involve the kidney in childhood; they also can occur primarily in the mediastinum or brain.^{145–147} Rhabdoid tumors of the kidney occur in infancy, with a median age at presentation of 13 months (range, 2 months to 5 years). Some rhabdoid tumors may be associated with the coincident development of PNETs

of the brain. Extrarenal rhabdoid tumors occur in older patients. The most common presentation is hematuria. Imaging shows a large, central, heterogeneous soft tissue mass that involves the renal hilum and has subcapsular fluid collections, tumor lobules separated by dark areas of necrosis or hemorrhage, and calcifications.¹⁴⁸ Metastasis, mainly found in the lungs, liver, and brain, is present in approximately 80% of those diagnosed.¹⁴⁹ Outcome is particularly poor, and there is no proved chemotherapy regimen. Abnormalities in the *hSNF5/INI1* tumor suppressor genes on chromosome 22 are typically found.¹⁵⁰ The tumor is characterized grossly as poorly circumscribed and soft with areas of hemorrhage and necrosis.¹⁴⁹ Histopathologically, these tumors have a rhabdomyosarcomatoid or myoblastic appearance, but the tumors do not express muscle markers and are not myoblastic in origin. The survival rate is almost zero, and even patients with stage I disease fare poorly. Therefore, patients should undergo aggressive therapy including surgical resection, local radiation therapy, and systemic chemotherapy. Because these tumors have been refractory to historical protocols, use of experimental dose-intensive chemotherapy regimens or new chemotherapeutic agents is warranted. A study of NWT5-5 looks at surgery followed by carboplatin and etoposide and alternating with cyclophosphamide for 24 weeks, and radiotherapy. Preliminary results show overall survival of 25.8%.^{151,152} Current COG studies are looking at regimens for metastatic disease.

Congenital Mesoblastic Nephroma

Congenital mesoblastic nephroma was first described by Bolande¹⁵³ in 1969 and differentiated from Wilms tumor. This tumor usually occurs in infants and typically follows a benign course; however, well-documented cases have resulted in metastases and death. It usually presents as a palpable abdominal mass on physical exam and less often hematuria. However, many cases are diagnosed using prenatal ultrasound.¹⁴⁹ Imaging shows a large, intrarenal mass with cystic hemorrhagic or necrotic foci. Mesoblastic nephroma has been reported in adults and in patients with Beckwith-Wiedemann syndrome. A translocation, t(12;15), has been reported and is associated with an *ETV6-NTRK3* gene fusion that may link mesoblastic nephroma to congenital fibrosarcoma.¹⁵⁴ Histologically, the tumor consists of bundles of spindle cells, tubules of basophilic cells, and invasion into the renal parenchyma or perinephric soft tissue. The cells resemble fibroblasts or smooth muscle. Congenital mesoblastic nephroma is usually curable by radical nephrectomy alone. Wide surgical margins are essential as this tumor often infiltrates locally into perinephric tissues. Tumors with high cellularity on light microscopic examination, however, and those with evident metastases, require more aggressive treatment. In particular, older patients with densely cellular lesions or high mitotic indices should be considered for systemic chemotherapy.

Renal Cell Carcinoma

There are several reported series as well as scattered case reports of renal cell carcinoma (RCC) occurring in childhood, adolescence, and young adults. In one study,¹⁵⁵ the median age was 15.5 years (range, 3–21 years). Histologically, the tumor is an adenocarcinoma similar to that seen in older patients. Most reported cases are of the clear cell variant of renal adenocarcinoma. There is no predilection for the right or left side, and the tumors are equally distributed between upper and lower poles and midkidney. Bilateral disease is associated with von Hippel-Lindau syndrome. Genetic abnormalities lead to approximately 33% to 50% of pediatric renal cell carcinomas, many of which include translocations involving chromosome Xp11.2. This translocation is considered

pathognomonic for pediatric RCC and results in the fusion of the *TFE3* gene.^{149,150} This subtype of RCC is similar to those of clear cell RCCs; however, they contain papillary structures, eosinophilic cytoplasm, and calcifications.¹⁴⁹ A further genetic abnormality described is t(6;11)(p21;q12) translocation tumors, which are less aggressive than those of Xp11.2.¹⁴⁹ Presentation is typically with hematuria, loin pain, and a palpable mass; however, approximately 25% are found incidentally on imaging. Imaging often shows a solid, nondescript lesion with little enhancement. There may be foci of hemorrhage and necrosis.¹⁴⁹ Sites of metastases include lung (64%), liver (57%), bone (42%), and pleura or brain (7%). Staging is based on the adult staging system, and survival is stage dependent. Unfortunately, many of these patients present with stage IV disease. Outcome analysis shows a correlation of survival with complete resection, although resectability was also associated with adverse prognostic factors such as lymph node involvement or distant metastases. Recommended therapy is complete resection by radical nephrectomy, if feasible. Recent studies show that partial nephrectomy has outcomes similar to radical nephrectomy in patients with stage I and II disease; however, longer-term data are necessary.^{156,157} In addition, immunotherapy has shown some beneficial effect on survival; however, further studies are necessary. The role of chemotherapy is undefined, but given the poor outcome associated with higher-stage disease, it is reasonable to administer postoperative chemotherapy as an experimental protocol. This should probably be performed as part of a national cooperative study.

RHABDOMYOSARCOMA

Epidemiology and Associated Conditions

In the United States, 850 to 900 children and adolescents younger than 20 years receive a diagnosis of soft tissue sarcoma each year, 350 of which are rhabdomyosarcomas.¹⁵⁸ Rhabdomyosarcoma is the most common soft tissue sarcoma in children younger than 14 years, accounting for almost 50% of soft tissue sarcomas in this age group. Two major histologic subtypes occur in childhood, embryonal and alveolar. Embryonal rhabdomyosarcoma constitutes approximately 75% of cases.¹⁵⁸ The alveolar subtype is more common in older children and extremity lesions. The incidence of rhabdomyosarcoma in the United States is 4 cases per 1 million white children younger than 15 years and approximately half that rate for black children.¹⁵⁹ The male-to-female ratio is 1.4:1, and 80% of patients are white, 12% are black, and 8% are of another race.

Rhabdomyosarcoma (RMS) can develop in any muscle throughout the body, and is the one tumor for which primary site affects survival.¹⁶⁰ Rhabdomyosarcoma has been observed in patients with neurofibromatosis and Beckwith-Wiedemann syndrome. The Li-Fraumeni cancer family syndrome involves the occurrence of sarcoma, in particular rhabdomyosarcoma, in addition to breast, bone, or brain cancer; lung and laryngeal cancer; and adrenocortical neoplasia. In this syndrome, children with rhabdomyosarcoma have first-degree relatives with the other malignancies. An autopsy study from the Intergroup Rhabdomyosarcoma Study (IRS) showed that 32% of patients with rhabdomyosarcoma had congenital anomalies that included (in order of frequency) genitourinary, central nervous system, and cardiovascular malformations.¹⁶¹ Also, basal cell carcinoma has been observed in conjunction with rhabdomyosarcoma.

Basic Science

The two histologic subtypes of RMS, embryonal and alveolar, are associated with individual genetic abnormalities that are

likely involved in tumorigenesis. Alveolar RMS has translocations between the long arm of chromosome 2 and the long arm of chromosome 13, $t(2;13)(q35;q14)$, which is present in approximately 55% of cases of alveolar RMS. The translocation results in the fusion of the *PAX3* gene, which is involved with transcription during neuromuscular development, with the *FKHR* gene, also a transcription factor but in the fork-head family. Another variant is with $t(1;13)(p36;q14)$, seen in approximately 22% of alveolar RMS, which gives rise to a *PAX7-FKHR* fusion in younger patients, mainly those with extremity lesions, and has a better prognosis. Abnormalities of the *PAX* gene cause abnormal muscle development. Currently, polymerase chain reaction (PCR) assays can confirm a diagnosis of alveolar RMS by detecting these fusion genes.^{162–165} No translocations have been reported for embryonal RMS; however, it is associated with hyperdiploidy and loss of heterozygosity at chromosome 11p15 or other genes.^{158,166}

Pathology

Rhabdomyosarcomas are malignant tumors that arise from the ubiquitously distributed primitive mesenchyme found in the fetus. These tumors display characteristics of striated muscle, including immunohistochemical expression of skeletal muscle myosin and actin, desmin, myoglobin, and Z-band protein. Electron microscopy may show actin–myosin bundles or Z-band material. Expression of the DNA-binding protein, MyoD1, has been shown to be a lineage marker for rhabdomyosarcoma.¹⁶⁷

Based on classic pathology, rhabdomyosarcoma has been divided into four main histopathologic subtypes: embryonal, alveolar, botryoid, and pleomorphic. The most common type in children is embryonal (75%). Botryoid tumors are really of the embryonal subtype but growing into a hollow space (e.g., vagina, bladder) so that they assume a characteristic grapelike appearance. Alveolar tumors are so named because of a resemblance to the microscopic structure of the lung (Fig. 109.9). Rhabdomyosarcomas are identified as alveolar if any alveolar elements are found in the tumor. Pleomorphic tumors usually occur in older adults. For all histologic types, sites of occurrence include the following: (a) head and neck (orbit, infratemporal fossa); (b) genitourinary tract, including perineum and perianal area; (c) extremities; (d) trunk (chest wall, paraspinal area); (e) retroperitoneum; and (f) biliary tract. Histologically, RMS is composed of small round blue cells, contains muscle-specific antigens including desmin and Myo, and is composed of eosinophilic rhabdomyoblasts.¹⁶⁵

FIGURE 109.9. Photomicrograph illustrating the typical lung-like appearance of an alveolar rhabdomyosarcoma. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1999, with permission.)

The initial biopsy should be generous enough for cytogenetic and immunohistochemical studies. Light microscopy alone is no longer adequate to secure the diagnosis and establish histopathologic subtype as polymerase chain reaction is used to detect translocations of minimal residual disease.¹⁶⁸

Presentation and Workup

The incidence of rhabdomyosarcoma is biphasic, with one peak in infancy followed by a second peak in the adolescent years. Presentation is site dependent. Head and neck lesions, found in approximately 35% of patients with rhabdomyosarcoma, can cause facial or cervical swelling and associated pain or skin discoloration. Sinusitis or middle ear infections can occur because the tumor blocks the normal drainage from these sites (i.e., sinusal ostia, eustachian tubes). Epistaxis, proptosis, or cranial nerve palsies may also be evident in head and neck lesions. Orbital sites, which occur in 75% of all head and neck tumors, have a favorable outlook in younger but not in older children. They are the least likely head/neck tumors to invade the meninges. Parameningeal involvement has a very poor outcome. Regional node sampling may be important in determination of risk status.¹⁶⁹

Genitourinary tumors can present with gross or microscopic hematuria, a suprapubic mass, and urinary tract infection or obstruction. Vaginal and cervical primary tumors often prolapse through the vaginal orifice as a friable polypoid mass and may hemorrhage.

Paratesticular lesions are most often observed in adolescence as a hard mass above and separable from the testis. Extremity tumors present as a painless or painful expanding mass, and there may be an associated limp or overlying skin change. Local bony invasion may result in pathologic fractures.

Rational management depends on a thorough pretreatment workup that completely defines local tumor extent as well as evaluating regional and distant sites of metastases. Table 109.7 lists the standard workup for pediatric patients with sarcoma. An extensive history, including a family history of malignancy, and a thorough physical examination are elementary. CT scans and MRI are used for evaluation of the primary tumor and metastatic disease. However, recent retrospective studies have shown PET to be an effective addition to the current imaging modalities, with a sensitivity of 77% and specificity of 95% for defining extent of disease.¹⁷⁰ Prospective studies are needed. Figure 109.10 depicts a CT scan of a large pelvic rhabdomyosarcoma originating from the bladder.

Staging

An evolution in sarcoma staging has occurred since the late 1980s, with most groups adopting the tumor, node, metastasis (TNM) system defined by the International Union Against Cancer. This staging system, which is used with the older IRS grouping, is listed in Table 109.8. The grouping system is listed in Table 109.9 and has been shown to be one of the main predictors of response to treatments.¹⁷¹ The TNM schema divides each stage into definable clinical components and is applied before any therapeutic interventions (although a second staging based on histologic findings of the primary tumor and regional lymph nodes after resection can also be performed). The IRS grouping schema is retained as well, although it remains operator dependent. The TNM system for rhabdomyosarcoma is unique in that it takes into account the site of disease origin, which affects prognosis.

The reported overall percentage of patients with tumors greater than 5 cm ranges from 50% to 68%, based on the TNM system. The proportions of other staging variables include invasive tumors, 37% to 71%; regional nodal involvement, 7% to 28%; and distant metastases at diagnosis, 20% to 23%.

TABLE 109.7**DIAGNOSIS****DIAGNOSTIC EVALUATION FOR SUSPECTED RHABDOMYOSARCOMA**

■ EXAMINATION OR TEST	■ RATIONALE
History and physical examination	Search for lymph nodes, size of primary mass, general condition, underlying conditions.
Complete blood count	Bone marrow replacement associated with anemia or thrombocytopenia; bone marrow toxicity is the major side effect of chemotherapy.
Electrolytes, renal and hepatic function tests, creatinine clearance	Renal toxicity associated with cisplatin and other alkylators; genitourinary tumors may obstruct ureters; hepatic toxicity with dactinomycin.
Four-site bone marrow aspirations, two-site bone biopsies	Bone marrow metastases reported in up to 6% of patients at diagnosis (29% of stage 4 patients have marrow involvement); bone marrow assessment before chemotherapy.
Bone scan	Possibility of bone and bone marrow metastases
CT scan of the primary site	Evaluation of tumor size, invasiveness, enlargement of regional nodes, and complicating ureteral, biliary, bowel, or airway patency.
CT scan of possible metastatic sites	CT scanning of the lungs and liver should be done to rule out parenchymal metastases. CT scanning is superior to MRI in assessing the degree of bone destruction in paraspinal, extremity, and head and neck (base of skull) lesions.
MRI	MRI is done for the same rationale as CT scanning. It may give more detailed information regarding the extent of viable tumor (T ₂ -weighted imaging) and the presence of hepatic metastases. It is also the most useful tool for evaluation of the epidural space in paraspinal or base of skull primaries.
Gallium scanning	Both the primary tumor and metastatic deposits may be identified by gallium scanning.

^aThe same workup is applicable to other high-grade sarcomas.
CT, computed tomography; MRI, magnetic resonance imaging.

It is preferable to sample metastatic regional lymph nodes, but extensive nodal dissections are not indicated. In the special case of paratesticular rhabdomyosarcoma, a limited dissection of ipsilateral, periaortic nodes is used as a determinant of the need for nodal radiation. The current recommendation for paratesticular rhabdomyosarcoma is for ipsilateral, nerve-sparing lymph node dissection, especially in boys older than 10 years at diagnosis, the cohort seriously understaged by

imaging studies alone. Patients 10 years or younger are staged with computed axial tomography. The use of sentinel lymph node mapping has been investigated for patients with RMS, and preliminary results are optimistic.^{172,173}

Excisional biopsy should be performed on small, accessible primary lesions, with the surgeon attempting to obtain a clear microscopic margin. Patients with larger infiltrating lesions or lesions for which removal would cause debilitation or deformity

RESULTS

SURGICAL-HISTOPATHOLOGIC CLINICAL GROUPING SYSTEM FOR THE INTERGROUP RHABDOMYOSARCOMA STUDIES I AND II

Group I	Localized disease, completely resected
A.	Confined to organ or muscle of origin
B.	Infiltration outside organ or muscle of origin; regional nodes not involved
Group II	Compromised or regional resection including
A.	Grossly resected tumors with “microscopic” residual
B.	Regional disease, completely resected, in which nodes may be involved and/or tumor extends into an adjacent organ
C.	Regional disease with involved nodes, grossly resected, but with evidence of microscopic residual
Group III	Incomplete resection or biopsy with gross residual disease
Group IV	Distant metastases, present at onset

Reprinted from Crist WM, Garnsey L, Beltangady MS, et al. Prognosis in children with rhabdomyosarcoma: a report of the Intergroup Rhabdomyosarcoma Studies I and II. Intergroup Rhabdomyosarcoma Committee. *J Clin Oncol* 1990;8(3):433–452, with permission. © American Society of Clinical Oncology.

(i.e., amputation or cystectomy) should undergo limited incisional or endoscopic biopsy. It is acceptable to perform transperineal needle core biopsies for bladder neck or perineal primary tumors. Enough biopsy material for light and electron microscopic analysis, immunohistochemistry, and cytogenetics should be obtained and frozen in liquid nitrogen as soon as possible after biopsy.

Risk Status

Presently the soft tissue sarcoma committee of the COG, the successor of the IRS, uses risk group assessment to determine therapy. Risk status is dependent on IRS group or stage but also age, anatomic location, and histopathology.^{174–176} Favorable anatomic sites include the orbit; nonparameningeal head and neck; paratestis; vagina and non-bladder-prostate genitourinary sites; and the biliary tract.^{177–179} High-risk sites include extremities, retroperitoneum, bladder-prostate, and parameningeal primaries.

Low-risk patients have embryonal rhabdomyosarcoma at favorable anatomic sites (stage 1, groups I, II, or III), or embryonal rhabdomyosarcoma at unfavorable sites but completely resected, or resected with only a positive microscopic margin (groups I or II). Intermediate-risk patients have embryonal rhabdomyosarcoma at unfavorable sites with residual gross disease (group III). The intermediate-risk group also includes patients with metastatic rhabdomyosarcoma who are younger than 10 years and patients with localized disease who have alveolar histology or undifferentiated sarcoma. High-risk patients have metastatic rhabdomyosarcoma or undifferentiated sarcoma at presentation, excepting patients younger than 10 years.

Treatment

- 6** The modern treatment of rhabdomyosarcoma is multidisciplinary and includes multiagent chemotherapy, judicious resection, and radiation therapy. The intensity of therapy should be tailored to the risk of subsequent relapse, which is a function of TNM stage. In general, agents are combined to limit drug resistance while attaining a synergistic antitumor effect.

A surgical procedure is typically done to confirm the diagnosis of rhabdomyosarcoma. However, often there remains gross residual tumor or positive surgical margins.^{180,181} Adequate margins of 0.5 cm should be obtained surrounding the tumor, which is easier to accomplish in tumors of the extremities or trunk. Clear margins are necessary but are not achievable when this would result in removing normal tissue that cannot be resected; or serious disfigurement or disability; or when it technically cannot be completed.¹⁸⁰

Surgical resection of the primary tumor was the mainstay of treatment 50 years ago but resulted in overall survival rates of only approximately 20%. The addition of chemotherapy improved the rate to 50%. Resection of primary tumors should be undertaken either before chemotherapy for small, noninvasive lesions or after documented response with more formidable primary tumors. An example of the operative approach for a lower extremity rhabdomyosarcoma involving anterior thigh muscles is depicted in Figure 109.11. In certain situations in which chemotherapy results in complete or very good tumor regression, external beam irradiation may be used as a primary means of local control. Even in these circumstances, it is important to obtain biopsy specimens to document complete tumor eradication. Debilitating or disfiguring surgery should be performed only if residual tumor is present after both chemotherapy and therapeutic irradiation. Amputation of extremity rhabdomyosarcomas does not enhance cure and should be performed only when lesions are bulky, invade bone or neurovascular structures, or are recurrent and cannot be resected by lesser procedures. Similarly, radical cystectomy is reserved for situations in which complete tumor eradication

FIGURE 109.11. Technique for resection of a proximal lower-extremity rhabdomyosarcoma. Longitudinal incisions are always used. It is important to excise the tumor completely, with a surrounding 1- to 2-cm margin if feasible.

has not been accomplished by chemotherapy and external-beam irradiation.

Second-look operations are often done after a partial response or no response to chemoradiation therapy, and after relapse. The guiding principle of rhabdomyosarcoma surgery is complete tumor resection, but removal of large amounts of normal tissue (i.e., muscle group resection, amputation) alone does not affect outcome.

The trend since the early 1990s has been to minimize treatment toxicity for genitourinary rhabdomyosarcoma.^{182–186} Currently, all patients with these tumors receive neoadjuvant chemotherapy after cystoscopic or transperineal biopsies confirm the diagnosis. This therapy is followed by repeat evaluations, including cystoscopic or percutaneous biopsies as well as imaging studies. A complete response after chemotherapy may obviate the need for external-beam radiation therapy in some cases, but most patients require local radiation. Surgery is reserved for recurrent or poorly responsive cases with residual gross tumor.¹⁸⁷ Exenterative cystectomy has decreased from more than 50% to 30% with the use of neoadjuvant chemoradiation.¹⁸⁸ When anatomically feasible, partial cystectomy is effective and preserves bladder function.¹⁸⁴ Newer techniques of urinary reconstruction involving stomas that can be catheterized may improve patients' quality of life.

Most patients with low-risk rhabdomyosarcoma are treated with vincristine and dactinomycin. Intermediate-risk patients receive cyclophosphamide in addition to these two drugs, and current studies are evaluating other agents. High-risk patients have a very poor outlook, and new therapies—including the use of irinotecan, melphalan, ifosfamide, and etoposide—are in development.

External-beam radiation therapy of the primary site or involved regional nodal echelons has contributed to locoregional control. All patients with group II to IV disease, in addition to group I alveolar tumors, receive radiotherapy.¹⁸⁹ Orbital and genitourinary primaries receive radiation therapy as the primary means of local control, with surgery reserved for very specific indications in patients with refractory or recurrent disease. Clinical data suggest that doses from 26 Gy to 50.4 Gy can be used in combination with chemotherapy. There is no difference in locoregional control rates between patients treated with conventional versus hyperfractionated radiotherapy.¹⁸⁹ Recent improvements in administration of radiation therapy include intensity-modulated radiation therapy (IMRT) and computer-modulated radiotherapy.^{190,191} The COG is currently studying “up-front” radiotherapy with chemotherapy administered earlier than currently given.¹⁶⁰

Outcome

The overall 5-year survival for children with rhabdomyosarcoma is approximately 64%. Table 109.10 lists the estimated 5-year failure-free survival and overall survival of patients with nonmetastatic rhabdomyosarcoma by prognostic factors based on the COG's Intergroup Rhabdomyosarcoma Studies III and IV.¹⁹² As expected, the presence of distant parenchymal metastases at diagnosis has an overwhelming adverse effect on survival, with 25% expected to be disease free after 3 years despite aggressive multimodality therapy.¹⁸⁰ Regarding site, most authors agree that orbital, paratesticular, and vaginal primary tumors are associated with improved outcome, whereas extremity, parameningeal, and truncal and retroperitoneal sites carry a worse prognosis. Survival is stage dependent.

Most studies conclude that overall and disease-free survival rates in rhabdomyosarcoma are equivalent; this means salvage after initial relapse is low and may depend on initial stage and histopathologic subtype. Therefore, primary therapy is crucial for long-term survival.¹⁹³ This suggests that, after risk assessment by staging, therapy should be as intense as possible to eradicate the tumor.

Future Directions

Myeloablative regimens with bone marrow or peripheral stem cell rescue have not improved overall outcome in patients with recurrent or metastatic disease.^{194–197} Biologic or immunologic therapy for rhabdomyosarcoma is not available. There is great interest in reducing the intensity of therapy for patients with low-risk tumors. Most clinical research for the worst-risk cases has focused on development of new chemotherapeutic regimens with activity against this tumor. There is also an interest in combining the use of chemotherapy and radiotherapy and in using pre-resection radiotherapy.

NONRHABDOMYOMATOUS SOFT TISSUE SARCOMAS

Epidemiology

Nonrhabdomyomatous soft tissue sarcoma (NRSTS) is a heterogeneous collection of tumors that accounts for 3% to 5% of pediatric tumors.¹⁹⁸ These tumors are different from rhabdomyosarcomas in histology, clinical characteristics, and prognosis. There is a bimodal age distribution, with tumors occurring most commonly in infants and adolescents, with slightly higher incidence among males. This group of tumors is composed of diverse histologic tumor types, no subtype of which represents more than 15% of all cases.¹⁹⁹ Since these tumors are rare, they are often analyzed as a group. The most common of the NRSTS tumors in children are dermatofibrosarcoma protuberans, malignant fibrous histiocytoma, synovial sarcoma, malignant peripheral nerve sheath tumor, and fibrosarcoma.

Pathology and Genetics

NRSTS are tumors of somatic tissue, derived from primitive mesenchyme. Table 109.11 characterizes these tumors. Each tumor type corresponds to normal cell types that develop from mesenchymal cells. The International Classification of Childhood Cancer has classified these tumors into four subgroups: fibrosarcoma category, Kaposi sarcoma category, the “other specified” soft tissue sarcomas, and the “unspecified” soft tissue sarcomas, none of which have any prognostic or therapeutic relevance.¹⁹⁹

© American Society of Clinical Oncology.

Presentation and Diagnostic Evaluation

Patients with NRSTS typically present with a painless mass that is often slow growing. Further symptoms may be present, secondary to compression by the tumor or invasion of adjacent tissues. Tumors that occasionally develop in the head and neck, such as fibrosarcomas, can be associated with swallowing and airways problems, which may require lifesaving tracheostomy. Approximately 15% of patients present with metastatic disease, most commonly in the lungs.²⁰¹ Bone marrow invasion is uncommon.

Workup for NRSTS begins with imaging, typically MRI, to provide anatomic definition; however, CT of the chest, abdomen, and pelvis is useful for staging. Core needle biopsies, which have higher sensitivity and specificity, are often used for diagnosis.^{202–204} In addition to routine histopathology, immunohistochemistry, cytogenetic and molecular studies, flow cytometry, and electron microscopy are recommended for accurate diagnosis.

Staging

There is currently no validated staging system for pediatric NRSTS. The Intergroup Rhabdomyosarcoma Study Group's

surgicopathologic system for rhabdomyosarcoma is often extrapolated to NRSTS. Staging systems for adults, which take into account tumor size, tumor extent, and tumor grade, are also used. The COG is currently working on a staging/grading system for NRSTS.

Treatment

The primary treatment modality for NRSTS is surgery. These tumors are resistant to chemotherapy and radiotherapy, so gross total resections are crucial when possible. A 1-cm margin is recommended. However, wide resections may not be attainable secondary to functional or cosmetic effects. When complete resection would require mutilating surgery such as amputation or laryngectomy, simple observation may be the best treatment. Often, the tumor mass is dormant for years, allowing growth of the affected part and the possibility of a less debilitating or deforming resection later. Radiation is often used to treat residual disease and has been shown to reduce the risk of local recurrence.²⁰⁵ Optimal dose and timing of radiation therapy is unclear. Although intraoperative radiation therapy (IORT) and IMRT have been used with

encouraging results, data for the pediatric population is inadequate. NRSTS tumors are chemoresistant; however, chemotherapy may be used in patients with unresectable disease with the goal of making these patients surgical candidates. Chemotherapy is also sometimes used for residual disease after surgery. It is also often used for patients with distant spread or at high risk for distant spread, although this use is controversial. Doxorubicin and ifosfamide are typically used.^{206,207} Novel therapies, including targeted therapies, are currently being studied, including antibody 8H9 in desmoplastic round cell tumors.

Outcome

Characteristics of NRSTS that affect outcomes include disease extent, histologic grade, tumor size, and degree of resection.^{201,208–214} Survival in patients with high risk or metastatic disease is approximately 15%. Survival in patients deemed intermediate risk (those with unresectable disease, or high grade with >5 cm) is approximately 50%. Patients with resectable tumors, or low risk, have a survival of approximately 90%.²¹⁵

HEPATIC TUMORS

Hepatoblastoma versus Hepatocellular Carcinoma

Epidemiology and Genetics. In Europe and North America, primary liver tumors constitute approximately 1.1% of childhood malignant neoplasms (1.4 cases per 1 million children in the United States).²¹⁶ The ratio of hepatoblastoma to hepatocellular carcinoma is variously reported from 1.3:1 to 6.5:1, accounting for approximately two thirds of all liver tumors in children.^{217,218} In areas endemic for hepatitis B, the ratio may be reversed and as low as 0.2:1. No geographic clustering of cases of hepatoblastoma has been noted. A male predominance is usually reported for both tumors, the ratio ranging from 1.5:1 to 3.1:1 for hepatoblastoma and from 1.3:1 to 3.2:1 for hepatocellular carcinoma. Between 1973 and 1997, 67% of hepatic malignancies in patients younger than 20 years were hepatoblastomas and 33% hepatocellular carcinomas.²¹⁹ Among children younger than 5 years, hepatoblastoma accounted for 91%. In children 15 to 19 years, hepatocellular carcinoma accounted for 87%. Hepatoblastoma is more common in children born premature than at full-term.^{220–222}

Hepatoblastoma occurs sporadically in adults, but the tumor usually presents in the first 3 years of life. Congenital presentation and antenatal diagnosis have also been reported.²¹⁸ Hepatocellular carcinoma, in contrast, is rare in infancy. The median age for diagnosis of hepatoblastoma in children is 18 months, whereas most cases of hepatocellular carcinoma are diagnosed after children are 10 years old.²²³ Historical series without pathologic review may report a higher rate of infantile hepatoma because of misdiagnosis of some early hepatoblastomas.

Hepatoblastoma has been linked to various genetic syndromes and familial conditions, such as familial adenomatous polyposis and Beckwith-Wiedemann syndrome.^{224,225} Erroneous imprinting at the 11–15 locus; alterations in the beta-catenin/Wnt pathway; and trisomies of chromosomes 2, 8, and 20 and rearrangements of chromosome 1 are seen in hepatoblastoma as well.^{226–231}

Clinical Presentation

Children with hepatoblastoma most commonly present with abdominal mass or diffuse abdominal swelling. Not infrequently, the child is in good health, and the lesion may be discovered on routine examination. Accompanying symptoms, such as pain, irritability, minor gastrointestinal disturbances, fevers, and pallor, occur in fewer patients. Significant weight loss is unusual, although patients may fail to thrive.

In contrast, although children and adolescents with hepatocellular carcinoma frequently present with palpable abdominal masses, these are rarely incidental. Pain is frequently present and can occur in the absence of an obvious mass. Constitutional disturbances, such as anorexia, malaise, nausea and vomiting, and significant weight loss, occur with greater frequency. Jaundice is an uncommon feature of either disease.

In most series of hepatoblastoma and hepatocellular carcinoma, a few patients present acutely with tumor rupture. Hepatoblastoma can present with sexual precocity caused by androgen synthesis or beta-HCG, although this is rare.

Laboratory Studies

Mild anemia is common in both conditions, and thrombocytosis is most often seen in patients with hepatoblastoma but occasionally in patients with hepatocellular carcinoma.²³² The cause for thrombocytosis in these conditions is unknown but may be related to release of tumor-derived cytokines.

Liver function test results are usually nonspecifically deranged in both conditions. A high serum cholesterol level is present in 50% to 60% of cases, and evidence suggests that higher elevations may correlate with a poorer prognosis. Beta-HCG is commonly secreted by liver tumors, and serum assays are often elevated. The most useful tumor marker is the serum α -fetoprotein (AFP). Elevation, often extreme, occurs in approximately 84% to 91% of cases of hepatoblastoma. Fewer patients with hepatocellular carcinoma have elevated AFP levels, and the elevation tends to be less marked. Patients with fibrolamellar variant of hepatocellular carcinoma rarely have elevated AFP. Although nonspecific for epithelial liver tumors, the AFP marker is used extensively to monitor both disease reduction in patients undergoing nonoperative therapy and disease recurrence in treated patients. Some reports concluded that a rise in AFP above normal in a patient with quiescent disease is more sensitive than radiology or surgical exploration to detect recurrence. Of note, AFP is often elevated in healthy children younger than 6 months and also may be elevated during liver damage, liver regeneration, or with other tumors.

Imaging Studies

Abdominal CT scanning is the investigation of choice both for diagnostic discrimination and to assess operability. The chest

FIGURE 109.12. Computed tomography scan of a 2-year-old child with a large right lobar hepatoblastoma (arrows). Despite the large size, these lesions can often be completely resected before chemotherapy. Hepatocellular carcinoma, in contrast, often involves multiple hepatic segments, and there is a significant incidence of extrahepatic extension.

should be included to identify pulmonary metastases. Hepatoblastoma typically appears as a solitary mass with lower attenuation values than a normal liver (Fig. 109.12). Dramatic contrast enhancement (as in benign vascular neoplasms), invasion of the portal vein, and lymph node involvement are unusual. Hepatocellular carcinomas have a similar appearance but are more likely to be multifocal, invade the portal vein, and metastasize to draining lymph nodes. Distinction between the two lesions cannot be definite because the pattern of disease may be atypical in either instance.

The diagnostic ability of MRI is similar to that of CT. The particular features of both hepatoblastoma and hepatocellular carcinoma on MRI are low signal intensity on T₁-weighted images and high intensity on T₂-weighted images. The two lesions cannot be distinguished by appearance alone.

Plain radiographs and liver-spleen scans usually indicate abnormalities but do not often contribute to diagnosis or assist in planning therapy. Angiography is indicated if embolization or infusion chemotherapy is contemplated, but this test is invasive, technically difficult in childhood, and not universally available. Similar information is available from dynamic CT scan or MRI such that these methods are considered adequate in most instances.

An abdominal ultrasound, in view of the low cost and ready accessibility, is probably the most useful screening investigation for children with large livers. This technique allows distinction between space-occupying lesions and diffuse hepatomegaly. Anatomic detail of the tumor margin is not usually sufficiently well delineated to assess resectability. Doppler ultrasound is also useful to evaluate patency of the inferior vena cava and hepatic veins, but extreme compression of these vessels may prevent useful interpretation.

The ability of imaging studies to predict resectability is questionable. Resectable lesions must usually be confined to the right lobe, right lobe plus medial left lobe, or the left lobe; in addition, the hepatic veins, inferior vena cava, and portal vein must be free of disease. On occasion, the distinction between compression versus invasion of liver adjacent to the lesion cannot be made, nor can the patency of vessels be established with certainty. In rare instances, it may be obvious that metastases in the remaining liver, portal or periaortic nodes, or other intra-abdominal organs preclude complete resection.

The available data do not establish any superiority of MRI or CT scan for evaluating the resectability of hepatic malignancies in children. In view of the possible advantage of

TABLE 109.12 STAGING**CHILDREN'S ONCOLOGY GROUP STAGING FOR HEPATOBLASTOMA**

Stage I	Complete resection
Favorable histology	Purely fetal histology with a low mitotic index
Other histology	All other stage I tumors
Stage II	Gross total resection with microscopic residuals or total resection with preoperative or intraoperative rupture
Stage III	Unresectable tumors as determined by the attending surgeon, partially resected tumors with macroscopic residual, or any tumor with lymph node involvement
Stage IV	Measurable metastatic disease to lungs or other organs

Courtesy of the Children's Oncology Group.

primary resection, a more reliable option is to judge resectability at formal laparotomy.

Early diagnosis by screening patients with genetic defects and families with hepatitis B is unlikely to have a major impact in Western nations. In Taiwan a program of early vaccination significantly reduced the incidence of hepatocellular carcinoma.^{233,234}

Staging

A staging system was derived and has been modified by the COG (Table 109.12) based on surgical findings and outcome of a primary operation before systematic therapy has been administered. Alternatively, a TNM classification has been proposed by the International Union Against Cancer and the American Joint Committee on Cancer and another by the Japanese Society for Pediatric Surgery. More recently, the PRETEXT (PRE-Treatment EXTent of disease) system has been advocated by SIOPEL (International Society of Pediatric Oncology Liver Tumor Group). This is a pretreatment, radiographic staging system that emphasizes the anatomic site of involvement as well as the number of involved Couinaud hepatic segments.²³⁵ A recent report from COG on the role of PRETEXT showed that COG stage and PRETEXT are good predictors of mortality and long-term survival.²³⁶

Pathology

Hepatoblastoma usually presents as a single, pseudoencapsulated lesion, often reaching large proportions before becoming clinically apparent. The tumor grows in an expansive fashion such that the umbilical fissure usually is not breached. Thus, despite a 30% to 40% incidence of bilobar disease, successful extended resection may still be possible. Multicentricity or massive diffuse disease within the liver occurs in less than 20% of patients, and cirrhosis of the surrounding liver is unusual.

In contrast, hepatocellular carcinoma usually lacks a distinct capsule. The tumor spreads diffusely through the liver in up to 70% of patients, often with satellite nodules well separated from the main tumor mass. Bilobar involvement occurs in 50% to 70% of cases, and the umbilical fissure does not constitute a

TABLE 109.13**COMPARISON OF RELATIVE RISK OF DEATH FOR HISTOLOGIC SUBTYPES OF HEPATOBLASTOMA**

HISTOPATHOLOGIC SUBTYPE	RELATIVE RISK FOR DEATH OF DISEASE ^a
Fetal	1.07
Embryonal	1.74
Mixed	0.53
Macrotrabecular pattern	1.20
Small cell undifferentiated	3.71

^aRisk of death adjusted for age, sex, and stage compared with other histologic subtypes.

barrier to spread. As a result, hepatocellular carcinoma is usually unresectable. Finally, because of the association of hepatocellular carcinoma with hepatitis B infection, cirrhosis may be present in the surrounding nonneoplastic liver. This may preclude complete tumor resection if the volume of liver to be removed is likely to compromise liver function further.

Hepatoblastoma is made up of embryonal-like cells, similar to hepatic stem cells. It contains five histologic subtypes including pure fetal, embryonal, mixed epithelial, mesenchymal/macrotubular, and small cell undifferentiated. The fetal subtype has the best outcome and small cell/undifferentiated the worst.²³⁷⁻²³⁹ One analysis showed that resected patients with pure fetal histologic type have a 2-year survival rate of 92%, which is significantly better than that for patients with embryonal or anaplastic tumor components (63% and zero 2-year survival rates, respectively).²⁴⁰ A comparison of the relative mortality risks for subtypes of hepatocellular carcinoma is listed in Table 109.13. In addition to the epithelial element, hepatoblastoma may contain varying amounts of immature stromal tissue, often containing osteoid.

The fibrolamellar subtype of hepatocellular carcinoma is characterized by broad fibrous septa that separate the cellular component into nodules and is most commonly seen in late childhood and adolescence. It is associated with a better prognosis and a higher resection rate. This difference, however, may not be independent of stage.

Of patients with hepatoblastoma, 10% to 20% present with distant metastases. The locations of metastases at autopsy in 46 patients in one report were the lungs in 46%, portal and periaortic nodes in 11%, brain in 7%, and peritoneum and diaphragm in 4% each.²⁴¹ The incidence of metastases is reportedly higher in patients with embryonal and anaplastic histologic types compared with fetal differentiation.

Hepatocellular carcinoma presents with metastatic disease in 30% to 50% of patients. The location of metastases at autopsy was reported by the Liver Cancer Study Group of Japan.²⁴² The lungs were involved in 48% of patients, lymph nodes in 37%, intraperitoneal organs in 16%, peritoneum in 15%, adrenal in 11%, bone in 10%, brain in 2%, and skin in 1%. Tumor emboli were detected in the portal vein in 59.7% and in the hepatic vein in 26.6% of patients. The higher incidence of lymphatic and intra-abdominal spread in hepatocellular carcinoma is relevant to local resectability and recurrence. Nodal disease in the porta hepatis and periaortic region is not readily resectable, and recurrence is inevitable if such disease is present.

Treatment

Hepatoblastoma. Complete surgical resection remains the major objective of therapy for hepatoblastoma (Fig. 109.12).

At presentation, approximately 60% of patients with hepatoblastoma have resectable tumors, and one review reported no survivors among children who underwent biopsy only or incomplete resection. More recently, sporadic patients who received nonoperative treatments have achieved complete response,^{243,244} and chemotherapy and radiation therapy have shown good results for some patients whose tumors were incompletely resected at the primary site.

A nonanatomic resection, wedging out the tumor with a satisfactory margin, may be feasible in the uncommon instance of a small peripheral or pedunculated lesion. More often, a major anatomic resection is required, depending on tumor location and extent. As much as 85% of hepatic substance may be removed, with subsequent full and rapid regeneration despite the administration of postoperative chemotherapy.²⁴⁵ The principles of safe hepatic resection are now well developed, and a considerable reduction in operative mortality rates has been possible since the 1970s. In two historical series, the mortality rate was reported to be approximately 22%, but in more recent series, it was as low as 0% to 3%.^{246,247}

The surgical principles include wide exposure using a generous bilateral subcostal incision and dissection at the liver hilum with isolation of vascular and ductal structures of the segment or lobe to be resected. After hepatic arterial and portal venous inflow to the relevant area is ligated, a color demarcation acts a guide to the correct plane of division of liver substance and allows this to proceed with minimal blood loss. Technologic advances such as the Cavitron Ultrasonic Surgical Aspirator (CUSA; Cooper Lasersonics, Santa Clara, CA) and metallic clip applicators have reduced the risk of hemorrhage, although finger-fracture technique with individual vessel and duct suture–ligation remains an acceptable alternative. Hemostasis of the transected surface can be completed with use of the argon beam coagulator or electrocautery and topical agents such as thrombin and Gelfoam (Pharmacia & Upjohn, Kalamazoo, MI). A trend to eliminate use of abdominal drains in uncomplicated cases has emerged.

Approximately 40% of patients with hepatoblastoma have inoperable tumors at presentation. Bilaterality, diffuse multicentricity, and metastatic lesions may all preclude resection. Various techniques have been used to increase the resectability rates, including preoperative chemotherapy, profound hypothermia with circulatory arrest, and total hepatic vascular occlusion. These maneuvers are a useful part of the surgical armamentarium in selected instances. During the 1990s, it became evident that some of these tumors may be rendered resectable by preoperative therapy. When the tumor is large, multicentric, has portal/hepatic venous involvement, or pulmonary metastasis, curative resection may be more likely after neoadjuvant chemotherapy.²³⁹ For truly unresectable disease, aside from transplantation, chemotherapy is the major treatment option available. If the tumor is unresectable at the time of the operation (stage III or IV), patients should receive four cycles of cisplatin, 5-fluorouracil, and vincristine, and then undergo either re-resection or transplantation. Doxorubicin is often added when the response is minimal. Furthermore, adjuvant chemotherapy is used after resection for patients with nonfetal histology stage I disease and stage II disease.

The role of radiation therapy is not clearly defined. In treating patients with bulky disease, the tolerance of normal liver is not compatible with the doses that would be required for tumor ablation, although temporary stability may be achieved. Hepatic toxicity has been described at doses to the whole liver of greater than 25 Gy. Focal radiation up to 45 Gy can be safely administered. There may be a place for radiation in a dose range of 25 to 45 Gy combined with chemotherapy in inoperable hepatoblastoma and in patients with postresection residual disease. In one report, eight patients were treated after incomplete resections (four with gross and four with microscopic residual disease) with combined irradiation and chemotherapy; six of these patients were free of disease at 4 to 83 months' follow-up.²⁴³

The use of liver transplantation in those with unresectable primary tumors is growing. A recent study showed up to 80% long-term disease-free survival in children receiving transplantation in large, solitary, or multifocal tumors invading all four sectors of the liver.²⁴⁸ The United Network for Organ Sharing database contains 237 patients from 1987 to 2006 who underwent orthotopic liver transplantation for hepatoblastoma. The median age of these children was 2.9 years. The overall survival at 1, 5, and 10 years was 80%, 69%, and 66%, respectively, with recurrence in approximately 50% of patients.²⁴⁹ Another recent multicenter study reviewed 147 patients with hepatoblastoma who had liver transplantation. Seventy-two percent of these patients underwent orthotopic liver transplantation as the first surgery, while the other 28% had an initial incomplete resection or had recurrent disease. The latter cohort had a worse outcome, with 30% overall disease-free survival versus 82% in those patients who received transplantation as their primary surgery.²⁵⁰ These results were replicated in other single-center studies.^{251–253} Patients, however, require long-standing immunosuppressive therapy after transplantation. In addition, the risk of hepatic artery thrombosis in transplant patients is 3 to 4 times greater in children than in the adult population.²⁵⁴ Recurrence and/or metastases are the primary causes of death in children with liver transplantation for hepatoblastoma, leading to 54% of deaths.²⁴⁹ Upcoming COG studies involve liver transplantation, and an international registry of all patients with childhood liver tumors has been established.

Other treatments with encouraging results are in developmental phases. Transcatheter selective arterial chemoembolization (TACE), which involves transarterial administration of chemotherapy in addition to a vascular occlusive agent, has been studied as potential neoadjuvant therapy in the hope of making unresectable disease resectable or for palliative therapy. The intra-arterial route allows the administration of agents directly to the tumor with the theoretic advantage of less systemic toxicity. One recent study looked at the feasibility and effectiveness of this technique. Cycles of cisplatin and Adriamycin mixed with lipiodol were given, followed with gelatin foam particles or stainless steel coils. TACE allowed for successive complete surgical resection in 13 of 16 patients and partial resection in the remaining three. Overall survival rates were 87.5%, 68.7%, and 50% at 1, 3, and 5 years, respectively. There was no major chemotherapeutic toxicity noted. Multicenter, randomized studies are needed.²⁵⁵

With improving management of the primary lesion, mortality is increasingly the result of metastatic relapse in the lungs. If metastases demonstrate progression or relapse on therapy, surgical resection is an option. Cure of pulmonary metastatic disease has not been demonstrated with radiation therapy. The use of pulmonary metastasectomy is not adequately studied in prospective studies; however, a recent report concludes that resection of lung metastases may be beneficial in patients with disease present at diagnosis that is not responsive to neoadjuvant treatment.²⁵⁶ Another series reported the operative treatment of five cases of pulmonary metastatic disease that developed after successful management of the primary tumor.²⁵⁷ All lesions developed during or soon after chemotherapy. Four patients were free of disease at 8 to 83 months' follow-up, despite having multiple lesions and requiring more than one resection in two cases. No patients with hepatoblastoma with metastases to sites other than lung or regional nodes have been reported cured.

Hepatocellular Carcinoma. Despite recent progress in the treatment of hepatoblastoma, treatment of children with hepatocellular carcinoma remains problematic and their outcome poor. Analogous to hepatoblastoma, complete surgical resection is a prerequisite for cure in hepatocellular carcinoma of childhood. Patients with incompletely resected tumors do not survive, as these tumors are very chemoresistant. In one study, the response rate to chemotherapy was less than 50%, with many patients having disease progression despite systemic

chemotherapy.²⁵⁸ Although patients undergoing resection survive longer than those who do not undergo resection, the gain is small owing to the high local and systemic relapse rates. The Japanese Liver Cancer Study Group reported a 40% 1-year survival rate for resectable disease and 10% for unresectable lesions.²⁴²

Stage for stage, the prognosis of hepatocellular carcinoma is no worse than that for hepatoblastoma. Many more patients present with advanced hepatocellular carcinoma, however, because the prevalence of bilobar and multicentric tumors and extrahepatic extension renders them unresectable. Nodal and systemic metastatic disease is more common at the outset. The liver may be cirrhotic in some instances, precluding an extensive resection short of transplantation.

Most series report the percentage of children with resectable hepatocellular carcinoma (HCC) to be approximately 10% to 20%. Patients with fibrolamellar histologic pattern may be an exception, with a resection rate of 48% to 60%, and essentially no association with cirrhosis. Relapse after resection is common. A POG and CCG intergroup study showed no impact of either cisplatin plus doxorubicin, or cisplatin, vincristine, and 5-fluorouracil on outcome in patients with hepatocellular carcinoma. The overall survival rate in the pediatric age group for hepatocellular carcinoma is rarely reported to exceed 20% and more realistically approaches zero. A role for external-beam radiation therapy has not been established. Only temporary stability of bulky disease has been demonstrated, and radiation has also failed to decrease the relapse rate in patients with minimal disease after surgical resection. Intra-arterial chemotherapy and chemoembolization have been used for patients with HCC as well, although studies do not show great responses. In addition, metronomic chemotherapy and adjuvant antiangiogenic treatments are currently under investigation and are preliminarily showing promising results.^{239,259-261} Given the poor results for conventional therapy, there may be a place for liver transplantation. However, transplantation is limited to tumors that fulfill the Milan criteria (single tumor ≤ 5 cm in diameter or up to three tumors each 3 cm or less in diameter, absence of macroscopic portal vein invasions, and absence of extrahepatic disease). These criteria are often used for adults, and it is unclear if they should be altered for the use of transplantation in children. The United Network for Organ Sharing database from 1987 to 2006 contained 41 pediatric patients with HCC who received orthotopic liver transplantation. The overall 1-, 5-, and 10-year patient survival rates were 86%, 63%, and 58%, respectively. As with hepatoblastoma, the main cause of mortality was relapse; however, relapse occurred more frequently in those patients with HCC (compared to the 54% in hepatoblastoma).²⁴⁹

Outcome. After a successful complete surgical resection, the 5-year event-free survival is 83% versus 41% for those patients with residual tumor after surgical resection.²⁶² Classifying tumors by grade, the COG has shown a 3-year event-free survival of 90% for stage 1 or 2 disease, 50% for stage 3 disease, and 20% for stage 4 disease.²⁶³ These patients have better outcomes than those with HCC, as a recent COG trial showed a 5-year overall survival of those with stage 1 tumors is 88%, stage 3 tumors is 23%, and stage 4 tumors is 10%.²⁶⁴

CHAPTER 110 ■ THE PREGNANT PATIENT

COSMAS J. M. VANDEVEN, N. SCOTT ADZICK, AND ALEXANDER S. KRUPNICK

KEY POINTS

- 1 The general surgeon should be familiar with the physiologic changes associated with pregnancy in order to distinguish maternal physiologic changes from signs or symptoms of disease.
- 2 When the uterus reaches the umbilicus, precise assessment of gestational age is recommended, which may require consultation with the obstetric service. Fetal monitoring should be considered to optimize uterine physiology, starting at approximately 20 weeks of gestation.
- 3 Concerns regarding medicolegal repercussions should not interfere with the proper medical care of the pregnant patient. Optimal care, including imaging studies, surgery, and the use of medications, benefit the mother and therefore the unborn child.
- 4 Perforated appendicitis in pregnancy rapidly leads to diffuse peritonitis, premature labor, and fetal loss. The rate of preterm labor and fetal loss with perforated appendicitis ranges from 26% to 66%, compared with 0% to 5% for uncomplicated appendicitis.
- 5 Laparoscopic cholecystectomy is a safe and reliable modality to treat gallstone disease during pregnancy. Symptomatic cholelithiasis treatment during the first trimester includes conservative measures until elective cholecystectomy can be performed safely during the second trimester of gestation. Second trimester disease can be dealt with surgically, whereas that presenting later in gestation can probably be managed symptomatically until the postpartum period.
- 6 Adhesions are the most common cause of intestinal obstruction in the gravid patient, but intestinal volvulus is a much more common complication than in the population as a whole. Intussusception, hernia, and carcinoma are responsible for a minority of cases of bowel obstruction.

In the United States alone, approximately 13 million conceptions occur annually, resulting in over 4 million live births each year.¹ Despite the continuous presence of this patient population, little emphasis has been placed on educating the general surgeon in the diagnosis and treatment of surgical problems in the pregnant patient. Although obstetricians routinely deal with pregnancy-related maternal disease and surgery, in many medical and surgical diseases the general surgeon is consulted. It is therefore imperative that he or she understands the normal physiologic changes occurring during pregnancy as well as the presentation of surgical disease in pregnancy. The surgeon often is the first person to evaluate a pregnant patient after trauma or for abdominal pain or learns of the pregnancy during the initial workup. The incidence of most surgical diseases remains the same in the pregnant patient, although some, like cholelithiasis, may actually increase. In addition, the surgeon must be aware of the changes in presentation as well as be conversant with the safety and utility of diagnostic imaging modalities. Pathways and algorithms for diagnosis and treatment of diseases in the nonpregnant woman must be altered to ensure the safety and well-being of the mother as well as that of the fetus. The purpose of this chapter is to review the physiologic changes that occur in pregnancy, discuss the risks and benefits of diagnostic imaging modalities and medications in pregnancy, and review the role of fetal monitoring and assessment of preterm labor. In addition, the presentation, frequency, and treatment of some common surgical diseases during pregnancy as well as their adverse effects on the pregnancy are described. Pregnancy is one of the rare situations when surgical decisions directly affect the lives of two people, and although mistakes can be twice as costly, rewards can double.

UTERINE PHYSIOLOGY AND PRETERM LABOR

Full-term delivery is delivery at 37 weeks of gestation or beyond. Twelve percent of live births are premature, at less

than 37 weeks of gestation. Seventy-five percent of all perinatal morbidity and mortality is associated with premature delivery.²

The uterus is a smooth muscle organ responsible for reception, implantation, development, and expulsion of the fetus. In the nonpregnant woman, the uterus is an exclusively pelvic organ weighing approximately 70 g with a cavity volume of 10 mL. During pregnancy, the uterus gradually becomes an intra-abdominal organ weighing close to 1,100 g and expanding to a total volume of 5 L at term. By the 12th week of gestation, the uterus becomes too large to reside exclusively in the pelvis and extends into the abdominal cavity. By the 20th week, the uterine fundus reaches the umbilicus; by the third trimester, it reaches almost to the liver (Fig. 110.1). As the uterus continues to rise, it exerts pressure on the anterior abdominal wall, displaces the intestines superiorly and laterally, and changes the relationship between the abdominal visceral organs. In the upright position, the uterus is supported by the anterior abdominal wall and usually undergoes a dextrorotation because of the presence of the rectosigmoid on the left. In the supine position, most of the uterine weight falls on the spinal column, but compression of the surrounding great vessels, especially the flaccid inferior vena cava, can occur.

Uterine activity and contractions are coupled to the electrical changes in the myometrium, which is physiologically arranged to maximize the efficiency of uterine contractions for the expulsion of the fetus at term. The resting membrane potential of the uterine myocyte ranges from -40 to -60 mV. It becomes more negative (-60 mV) early in gestation and increases to -40 mV near term. Early in pregnancy, the myometrium exhibits irregular electrical activity, termed *slow waves*. These rhythmic alterations in the membrane potential occasionally reach the threshold potential and lead to an action potential at the top of the slow wave. Entry of Ca^{2+} through voltage-sensitive Ca^{2+} channels allows for actin-myosin interaction and electromechanical coupling, leading to uterine contraction. By the second trimester, irregular contractions can be palpated through the abdominal wall and are known as Braxton Hicks contractions.³ These irregular contractions during

FIGURE 110.1. Enlarging uterus during gestation. At 12 weeks, the uterus rises out of the pelvis into the abdomen. At 20 weeks, the fundus is at the height of the umbilicus, and at 36 weeks the uterus reaches to the upper abdomen.

pregnancy lead to relatively small increases in uterine pressure and do not result in cervical effacement or dilatation. At term, gap junctions are formed between the uterine myocytes, which allow for electrical and metabolic communication. The increase in gap junctions results in rapid and efficient conduction of the action potential throughout the uterine smooth muscle with resulting coordinated, purposeful contractions generating pressures up to 80 mm Hg. These coordinated contractions ultimately result in effacement and dilatation of the cervix and delivery of the baby.

The mechanisms behind human parturition are still poorly understood. Numerous hormones, peptides, and local mediators act on the myometrium both to stimulate and down-regulate its activity (Table 110.1). Parturition begins when forces favoring uterine activity override those of quiescence and tip the balance toward contraction and ultimately birth. Progesterone maintains uterine relaxation during most of the pregnancy by blocking Ca^{2+} flux through cell membranes and opposing the action of estrogen. Close to term, the concentration of estrogen increases relative to that of progesterone, leading to uterine activation. Synthesis and surface expression of contraction-associated proteins, including gap junctions, ion channels, and oxytocin receptors, is initiated, and the uterus is transformed from its pliable, relaxed state to one of responsiveness and excitability. A shift in arachidonic acid metabo-

lism from lipoxygenase products to those of cyclooxygenase, especially prostaglandin E_2 and $\text{F}_{2\alpha}$, favors activation of the uterine musculature as well as the onset of uterine contractions. Prostaglandins raise local Ca^{2+} concentrations by increasing Ca^{2+} flux across the cell membrane and stimulating Ca^{2+} release from intracellular stores. Inflammatory cytokines, especially interleukin (IL)-1 and IL-6, are produced locally by placental tissues and act in concert with other stimulatory factors to propagate uterine activity.^{3,4}

Oxytocin is a nonapeptide synthesized in the hypothalamus and secreted from the posterior pituitary. Its name means “quick birth,” and it was the first uterotonic to be implicated in parturition. Oxytocin stimulates Ca^{2+} flux across myometrial plasma membranes and has distinct receptors located in the myometrium and other reproductive tissues. Uterine responsiveness to oxytocin is directly related to receptor concentration, which can increase 300-fold during pregnancy. The uterine smooth muscle surface expression of oxytocin receptors is increased by maternal estrogen and opposed by progesterone. Although it was originally isolated from the posterior pituitary, the placental content of oxytocin is approximately five times that of the pituitary, and the placenta is most likely the main source of oxytocin during pregnancy and parturition.⁴

Preterm Onset of Labor

Preterm onset of labor is uterine contractions producing cervical change prior to 37 weeks of gestation. Despite many attempted interventions, the rate of premature deliveries has increased in the last 40 years and is currently about 12%.² Prematurity is responsible for 75% of all neonatal morbidity, mortality, and cost of neonatal care.⁵ Survival has increased with improvement in neonatal intensive care units, but the premature infant still experiences a wide variety of ailments with long-term sequelae in many organ systems.

The cause of preterm labor is often multifactorial, but the onset of labor during surgical manipulation or intra-abdominal inflammatory processes is of most concern to the surgeon. Increased prostaglandin production in the presence of an infective process can activate preterm labor. Bacterial infection of the amniotic tissues or peritoneum leads to a local increase in eicosanoids and the onset of labor.⁶ Endotoxin acts on inflammatory cells to increase production of IL-1 and IL-6, which also amplify local prostaglandin production. All these factors can act in concert to initiate and propagate preterm labor. Uterine activation and increased expression of gap junctions as well as oxytocin receptors can be induced by uterine stretch.⁷ Uterine trauma caused by surgical manipulation could affect these same mechanisms, leading to premature uterine contractions. The interrelations at various levels between the inflammatory response, uterine and maternal trauma, and the initiation of labor can represent the body’s attempt to expel the fetus from a hostile intrauterine environment.

Tocolysis

Tocolytic therapy attempts to reverse or alleviate the premature onset and/or progression of labor. In most clinical presentations, the etiology of the preterm onset of uterine contractions is not known. Intervention is directed at decreasing the uterine smooth muscle activity through inhibition of the muscle contraction. Despite 40 years of research, there has been little success in the prevention or treatment of preterm labor. Tocolytic treatments may result in the delay of delivery by approximately 48 hours, which allows for the administration of steroids to promote fetal lung maturation through the release of surfactant. The use of antenatal steroids is associated with a decreased risk of respiratory distress syndrome and multiorgan failure in the preterm neonate.⁸ Prostaglandin synthesis

inhibitors, magnesium sulfate, β -adrenergic agonists, and calcium channel blockers are the four most common pharmacologic agents used as tocolytics.⁹ The choice of tocolytic agent may vary between institutions.

Magnesium sulfate is often used as a first-line tocolytic agent when the onset of premature contractions is documented. Most data support the theory that magnesium exerts its effects by calcium antagonism. High intracellular magnesium concentrations inhibit Ca^{2+} entry into myometrial cells, interfering with actin–myosin coupling. High magnesium concentrations also increase the sensitivity of K^{+} channels, favoring hyperpolarization and uterine relaxation. Maternal serum levels necessary to inhibit myometrial contractility are not well established but may range between 4 and 9 mg/dL, two to six times normal levels. These serum concentrations of magnesium needed for tocolysis are not far from levels causing ablation of deep tendon reflexes (9 to 13 mg/dL) or respiratory depression (14 mg/dL). Concern regarding magnesium toxicity requires careful monitoring of the patient, particularly in patients with compromised renal function.

Because of the importance of prostaglandins in the promotion of uterine contractions, prostaglandin synthetase inhibitors, especially nonsteroidal anti-inflammatory drugs, are used to stop premature labor. Indomethacin is the nonsteroidal drug used most frequently for tocolysis because of its quick onset of action and ease of dosing.

β_2 -Adrenergic agonists used in the treatment of preterm labor include ritodrine and terbutaline. Stimulation of uterine β_2 receptors leads to activation of adenylate cyclase and an increase in intracellular cyclic adenosine monophosphate (cAMP) concentration. Activation of cAMP-dependent protein kinase A inhibits myosin light-chain phosphorylation and actin–myosin coupling. Protein kinase A activity is also associated with increased Ca^{2+} efflux, decreased Ca^{2+} influx, and increased K^{+} conductance. All these actions lead to myometrial relaxation.

Calcium channel blockers inhibit entry of calcium through voltage-dependent Ca^{2+} channels. The use of oral nifedipine can abolish uterine activity and prevent delivery with minimal toxicity or side effects.

The role of tocolytic therapy remains controversial. The benefit appears to be limited to delaying premature delivery by 48 hours, allowing for administration of steroids to enhance fetal lung maturity. Maternal and fetal side effects can be serious, so close observation is necessary with all forms of tocolysis. The decision to use tocolytics must be made only after the diagnosis of premature onset of labor is confirmed and the benefits of prolonging gestation outweigh the risks of tocolysis.

When nonobstetric surgery is required in a pregnant patient, prophylactic use of prostaglandin synthesis inhibitors such as indomethacin is recommended. A preoperative dose of 50 to 100 mg of indomethacin can be administered orally. Postoperative continued prophylaxis using indomethacin 50 mg by mouth, every 6 hours for a total of 48 hours, should be considered.

For intra-abdominal surgery in the preterm pregnant patient, preoperative steroid administration should be considered. Either two doses of betamethasone 12 mg, 24 hours apart, or four doses of dexamethasone 6 mg, 12 hours apart, should be administered to the mother, ideally beginning 48 hours prior to surgery.⁸

PHYSIOLOGIC CHANGES OF PREGNANCY THAT MIMIC DISEASE

The maternal physiologic homeostasis adapts in order to promote a physiologic environment that benefits the development and growth of the fetus. These physiologic changes may mimic or mask the diagnosis of medical disorders.

Progesterone levels increase throughout the pregnancy.³ Progesterone is a smooth muscle relaxant that plays a major role in assuring relaxation of the uterine smooth muscle in order to prevent premature delivery. In addition, vascular, gastrointestinal, and urogenital smooth muscle relaxes, resulting in common pregnancy-associated signs and symptoms. Progesterone-induced smooth muscle relaxation appears to be dose dependent and can be blocked by increasing the extracellular concentration of Ca^{2+} , at least in vitro, suggesting that progesterone may alter the effective Ca^{2+} available for actin–myosin coupling.¹⁰

Plasma volume increases by up to 50% and red blood cell volume by 20% to 30%. This increase in intravascular (blood) volume leads to a 50% increase in cardiac output (CO).¹¹ In order to allow for this increase in CO, pregnancy is associated with marked venous and arterial vasodilatation. Vasodilatation occurs to such an extent that the blood pressure actually decreases during pregnancy, with the nadir around 24 weeks and a return to baseline by term.¹² Vasodilatation is facilitated by a decrease in vasoconstrictor sensitivity and an increase in the production of nitric oxide and prostacyclin.¹³ Common clinical signs and symptoms associated with this increase in CO and associated vasodilatation include decreased exercise tolerance, mild peripheral edema, spider angiomas, complaints of stuffy sinuses, an increase in lower extremity varicosities, and hemorrhoids.

In order to increase oxygen delivery to the fetus and remove the increased supply of CO_2 produced by the fetus, the mother hyperventilates throughout the pregnancy.¹⁴ Arterial pO_2 values increase while pCO_2 levels decrease, and pH increases (mild alkalosis). Maternal oxygen metabolism increases by 20% to 30% and functional reserve capacity decreases. Therefore, a pregnant patient may desaturate much quicker compared to a nonpregnant patient. When intubation is needed, there is significantly less time to establish an airway and assure continued oxygenation of the mother and baby. Fetal CO_2 is cleared by passive diffusion. In case of mechanical ventilation, maternal pCO_2 levels should be targeted at lower levels in order to prevent acidosis of the fetus. It is common for the pregnant patient to have the sensation of shortness of breath, specifically in the second and third trimester when the uterus increases in size and displaces the diaphragm upward.

The lower esophageal sphincter tone gradually decreases, as does gastric emptying time. Nausea and vomiting of pregnancy is a common occurrence affecting between 50% and 90% of all women.¹⁵ This correlation with pregnancy was documented as early as 2000 BC. Although a clear cause has not been established, it rarely extends beyond the first trimester. Other causes must be investigated if the nausea and vomiting persist or occur later in pregnancy.

The gallbladder empties more slowly during pregnancy and undergoes a gradual increase in residual volume, both during fasting and after meals. With these changes, combined with supersaturation of bile by cholesterol, pregnancy becomes a lithogenic state.¹⁶ The effects of pregnancy are transient, and gallbladder motility and volumes return to normal as early as 2 weeks after pregnancy, but the gallstones, if formed, may persist.

Prolonged small bowel transit time and decreased colonic emptying work to maximize nutrient and water absorption but also contribute to the constipation reported by 38% of pregnant women.¹⁷

Abdominal pain may be related to a surgical pathologic process but can have many pregnancy-associated causes.¹⁸ Round ligament pain is described as an aching, dragging pain that typically is unilateral. It is provoked by physical activity or even turning while sleeping. It is a common occurrence until the third trimester. Pain in the hypochondrium can result from uterine pressure on the lower ribs. The patient describes a very localized, sharp, nonradiating pain that more often is on the right compared to the left upper quadrant.

Hemoglobin concentrations may drop to 10 mg/dL, and hematocrit values may go as low as 30%. Pregnancy may be associated with an increase in the white blood cell (WBC)

TABLE 110.2**CHANGE IN LABORATORY VALUES DURING PREGNANCY**

■ PARAMETER	■ CHANGE	■ NORMAL NONPREGNANT VALUE	■ LATE PREGNANCY VALUE

count, up to levels of 13,000 WBCs per mL. Intrapartum and immediate postpartum (<24 hours) counts may be as high as 25,000 WBCs per mL. Platelet counts may slightly decrease as the pregnancy progresses. Thrombocytopenia is relatively common (up to 8%) in pregnancy. The most common cause is gestational thrombocytopenia.¹⁹ The patient is typically asymptomatic, and platelet counts recover to normal levels within a few weeks following the delivery. Renal blood flow and glomerular filtration rates increase by over 50%. Creatinine levels decrease appropriately, resulting in normal levels of 0.5 to 0.6 mg/dL. Serum alkaline phosphatase levels gradually increase because of production of an alkaline phosphatase isozyme by the placenta. This does not reflect biliary or bone disease. Albumin levels may be lower, associated with the increase in plasma volume, and osmotic pressure may be decreased (Table 110.2).

IMAGING MODALITIES IN THE PREGNANT PATIENT

Advances in radiology have revolutionized surgical practice. By visualizing the lesion before exploration, surgical intervention can focus on the area of disease or avoid it altogether. Emergency medicine physicians, radiologists, and surgeons are frequently hesitant to use the proper diagnostic imaging modalities for pregnant patients because of the perceived danger to the developing fetus. In almost all clinical presentations, the risks of misdiagnosis by avoiding the proper imaging tests are greater compared to the risks of sequelae from ionizing radiation to the fetus. The physician should not avoid proper diagnostic and therapeutic interventions because of medico-legal concerns. Although experimental data regarding the effects of ionizing radiation on the developing human fetus are impossible to obtain, animal exposure and follow-up of those inadvertently exposed to radiation have provided some information: Retrospective studies of atomic bomb survivors in Hiroshima and Nagasaki have allowed for evaluation of the effects of massive radiation exposure in utero.²⁰

Ionizing Radiation

Fetal effects of ionizing radiation depend on the dose absorbed by the fetal tissue and the stage of fetal development during exposure. Exposure is defined as the amount of ionic charge created by the radiation on passing through a defined mass of air. The roentgen is a common unit of exposure, producing 0.26 millicoulomb per kilogram of air or 2 billion ion pairs per cubic

centimeter of exposed air. Although exposure is useful for measuring radiation output, the absorbed dose is the radiation imparted to tissue that creates a biologic effect. One gray (Gy) is strictly defined as the deposition of 1.0 joule of energy per kilogram of tissue. One rad is 1% of 1 Gy. As a gross estimate, exposure to 1 roentgen gives an absorbed dose of 1 rad or 10 mGy.

It is a misconception to assume that the radiation absorbed by the mother is the same as that absorbed by the fetus. Dosing of radiation to the uterus and conceptus can vary several fold based on abdominal wall depth and the anteverted or retroverted position of the uterus. Radiographic evaluation of the abdomen and pelvis is most likely to expose the fetus to direct ionizing radiation, whereas examination of the extremities and chest leads to exposure from scatter radiation only²¹ (Table 110.3).

Radiation-induced ionization of vital cellular structures can result in damage to the DNA. DNA damage may be repaired or may result in cell death, rapid cell growth, abnormal cell growth, or genetic mutation. Cellular destruction either leads to the death of the embryo if a significant amount of tissue is affected or has no effect if the damaged cells are replaced by healthy ones. Growth impairment of organs occurs if the population of cells cannot be replaced or damage occurs to a small population of progenitor cells at a vital stage of development. All these effects are produced at threshold doses, and exposure to radiation levels below the threshold does not have biologic consequences compared with control populations.²² The outcome of radiation exposure depends on the absorbed dose and the stage of

TABLE 110.3**RADIATION DOSING TO THE CONCEPTUS AND UTERUS FROM SELECTED RADIOGRAPHIC EXAMINATIONS²¹**

■ EXAMINATION	■ DOSE (mrad)
Routine chest radiograph	0.5–1.0

Computed tomography, pelvis	2,000

development during exposure, with potential death early in gestation, teratogenesis during organogenesis (4 to 10 weeks of gestation), and growth retardation at later gestational stages.

Lethal Effects

The multicellular embryo, before the blastocyst stage, is most sensitive to the lethal effects of radiation but resistant to teratogenesis if it survives. The cause of this phenomenon is uncertain but could relate to the totipotent nature of the embryo at this stage and its ability indiscriminately to replace a specific volume of tissue below the lethal threshold. Because more than 50% of all human pregnancies abort, mostly without any recognition that fertilization has even occurred,²³ determining the lethal dose of radiation at this stage is difficult. Significant radiation exposure in the first 2 weeks of human development, which corresponds to gestational weeks 3 and 4, results in loss of the pregnancy. If the pregnancy is not lost, the patient can be reassured that the risk for teratogenicity is very low.

Teratogenic Effects

Teratogenic effects of radiation can occur during early organogenesis in animal studies. Exposure of rats to 100 rads at various points of development reveals a very narrow window for teratogenesis. This window corresponds to weeks 2 to 8 in human development (4 to 10 weeks of gestation), consistent with early organ formation. Despite these experimental data, it is difficult to link any specific human malformation with radiation exposure other than those of the central nervous system (CNS). Microcephaly, pigmentary changes in the retina, hydrocephalus, and optic nerve atrophy have been reported at a significantly higher rate after exposure to radiation in pregnancy.²⁴ All patients were exposed to a minimum estimated dose of 100 rads, and no visceral, limb, or other malformations were found unless the child also exhibited CNS abnormalities. One explanation for this discrepancy is that the developmental period of the CNS is much longer, continuing throughout gestation and into the neonatal period, whereas other organs have a very narrow period during which morphologic alterations can be produced. Exposure to high doses of radiation during this narrow window is rare, and even if an isolated congenital abnormality were to occur, it would be difficult to separate this event from the background malformation rate. Current data suggest that exposure less than 5 rads does not increase the risk for birth defects. Although there is concern about teratogenicity of exposure from 5 to 10 rads, only exposure greater than 10 rads is proven to create serious risk to the fetus.²⁵

Intrauterine Growth Restriction

Intrauterine growth restriction results from radiation-induced cellular depletion. Although catch-up growth can occur if exposure happens early in gestation, permanent cell depletion and growth restriction occur with exposure during the second and third trimester.²⁶ Wood et al.^{27,28} studied growth retardation of children exposed in utero to the Japanese atomic blasts. Those within 1,500 m from the center of the explosion were exposed to over 25 rads and, when followed through age 17 years, were 2 to 3 cm shorter, 3 kg lighter, and had a head circumference 1 cm smaller than normal. Those beyond 1,500 m from the blast received less than 25 rads and had a normal head circumference, height, and weight. Further animal and human data support the contention that exposures of less than 5 rads should not cause either anatomic malformation or growth retardation.²²

Oncogenic Potential

The correlation between childhood cancer and in utero exposure to radiation has been reported,^{29,30} although conclusions regarding the cause-and-effect relationship of this correlation could not be definitively established. In addition, the severity of the effect appears unrelated to the dose. In analyses of Japanese A-bomb survivors who were exposed in utero, no significant increase in rates of childhood or adult cancer were reported.³¹ Expert consensus estimates the increased risk of lifetime cancer associated with at least 10 rad in utero exposure to increase by 1%, from 20% to 21%.³²

Ultrasound

Ultrasonography uses high-frequency, nonionizing, acoustic radiation to create images. A surface transducer sets up vibratory motions that are transmitted through matter as acoustic waves. The boundaries between different densities of tissue reflect some of these sound waves back to be detected by a transducer. Ultrasonic images therefore detect acoustic boundaries between different biologic materials in the body. Audible sound ranges from 20 to 20,000 vibrations per second, whereas ultrasonography uses frequencies of 1 million to 10 million vibrations per second. Since its initial use in the 1950s, diagnostic ultrasonography has not been shown to produce fetal damage or harmful effects;^{26,33} however, theoretic dangers do exist. Rapid compression and decompression of tissue by sound waves could cause tissue damage. Conversion of mechanical energy to thermal energy, especially at the bone-soft tissue interface, could lead to local hyperthermia, whereas the phenomenon known as cavitation could cause microscopic bubbles already present in tissues to grow in size because of absorption of surrounding diffused gases. However, there is no consistent evidence that properly used diagnostic ultrasound is detrimental to the conceptus.³³

Magnetic Resonance Imaging

Like ultrasonography, magnetic resonance imaging (MRI) uses no ionizing radiation and instead relies on the magnetic properties of tissues to create images. Four magnetic fields interact during an MRI examination to create the image. The intrinsic magnetic field of an atomic nucleus, usually that of a hydrogen proton, is combined with a strong, uniformly applied external magnetic field and a weaker magnetic field gradient. In addition, a magnetic field is intermittently generated by pulsed radiofrequency waves. When this external radiofrequency is applied to nuclei in an existing magnetic field, the nuclei absorb some of the energy and change their orientation. When the radiofrequency ceases, the nuclei return to their previous orientation and emit the radiofrequency they absorbed. These signals are detected, stored, and processed by a computer to create an image.

Based on current data, it is unlikely that magnetic fields of the intensity used for diagnostic MRI pose any danger to the developing fetus, but biologic mechanisms do exist that could, at least theoretically, lead to damage. Charged particles and molecules moving in a strong magnetic field create an electrostatic potential difference, and normal red blood cells can alter their shape and create a charge when moving within an electric field.³⁴ Changing magnetic fields can induce visual light flashes because of magnetic effects on the photoreceptors in the eye,^{34,35} and heat can be generated during the application of radiofrequencies. All these effects, however, occur with applications well above those used for diagnostic purposes. Based on these and other data, the International Radiation Protection Association has concluded that despite the lack of

evidence that mammalian embryos are sensitive to the magnetic fields encountered during MRI examination, elective examination of pregnant women by MRI should be postponed until after the first trimester and completion of organogenesis. Ultrasonography should be the diagnostic modality of choice during pregnancy, with MRI limited to cases in which unique diagnostic information is required.³⁶ MRI, however, is not absolutely contraindicated even in the first trimester in situations when ultrasound cannot suffice.

Medications in Pregnancy

Many pregnant patients will require medical interventions, including the use of medications. In contrast to common belief, most medications are relatively safe in pregnancy. Medications contraindicated in pregnancy include but are not limited to coumarin derivatives, isotretinoin, methotrexate, diethylstilbestrol, thalidomide, angiotensin-converting enzyme (ACE) inhibitors and ACE antagonists, tetracycline, and quinolones. However, the risks to the fetus may be less compared to the risk to the mother when not using the proper medication. Optimizing maternal physiology and maternal well-being almost always benefits the fetus. When medications are needed to accomplish this, the benefits most commonly outweigh the risks. Particularly in clinical emergencies or trauma, immediate initiation of the proper medications may be required to save the life of the mother and therefore the life of the fetus as well. Many resources are available to the clinician to assess the risks to the fetus.³⁷ The widely used Food and Drug Administration (FDA) classification is of limited value since it does not incorporate data from pregnancy registries and other resources.³⁸ The most detailed information is available through a national database called *Reprotox*. Consultation with the obstetric service may assist in choosing the optimal medications for both the mother and the fetus.

FETAL MONITORING

Fetal heart rate (FHR) monitoring is used in obstetric practice as an indirect assessment of fetal well-being. Electronic FHR monitoring was introduced in the late 1950s,³⁹ has gained wide acceptance, and is now used in over 85% of all pregnancies.⁴⁰ The FHR can be monitored externally, using a Doppler device that is placed on the maternal abdomen. Uterine activity is monitored by using a tocodynameter, also applied to the maternal abdomen (Fig. 110.2). Since direct evaluation of fetal oxygenation and acid-base status is not possible except for a few rare unusual circumstances, monitoring of fetal well-being is based on indirect methods. It is believed that the FHR patterns may change in response to altered uterine-placental perfusion or decreased oxygen content in the maternal blood. In trauma or during surgery, uterine perfusion or maternal oxygenation may be altered, and monitoring the FHR may assist the surgical team in correcting placental perfusion and oxygenation in order to improve the fetal status.

Internal fetal monitoring is used intrapartum and relies on analysis of fetal cardiac patterns from electrocardiogram leads placed directly on the exposed part of the fetus. A transcervical intrauterine pressure catheter may be used concurrently to monitor the strength of the uterine contractions.⁴⁰

Fetal Heart Rate Interpretation

A normal FHR during pregnancy ranges between 110 and 160 beats per minute (bpm). A prolonged baseline (≥ 10 minutes) above 160 bpm is considered fetal tachycardia, whereas that below 110 bpm is considered fetal bradycardia.⁴¹

FIGURE 110.2. Intraoperative and postoperative fetal monitoring using noninvasive surface Doppler and pressure sensor to monitor uterine contractions.

Accelerations are defined as an increase in the FHR of at least 15 bpm for at least 15 seconds. The presence of accelerations is reassuring. FHR accelerations are normal findings in the second half of pregnancy and occur as a result of increased sympathetic and decreased parasympathetic stimulation with fetal movements.

Changes in blood pressure and oxygenation are detected by the chemoreceptors and baroreceptors of the aortic arch and carotid bodies, resulting in a change in the heart rate to maintain a steady state. Normal FHR tracings express continuous adjustment in the vagal tone through variability in the heart rate. The FHR demonstrates continuous variability from the baseline, with fluctuations of peaks and troughs ranging from 6 to 25 bpm. Decreased heart rate variability can be a physiologic response of the fetal sleep-wake cycle or maternal medications such as sedatives. Persistently decreased variability may be associated with altered fetal perfusion or oxygenation. Decelerations usually occur intrapartum and are related to the uterine contractions (periodic decelerations). The decelerations are classified as “early,” or simultaneous with the contraction; “late,” or starting when the contraction is in progress and recovering after the contraction is over; and “variable,” or variable in relation to the contractions. Early decelerations are uniform, gradual drops in the FHR that mirror the uterine contractions and reflect an increased vagal tone from a transient increase in intracranial pressure. This pattern is a benign physiologic manifestation of a functioning autonomic nervous system and is not associated with adverse outcome. Variable decelerations result from umbilical cord compression by uterine contractions. Isolated variable decelerations have little clinical significance, but if persistent with inadequate recovery between contractions, intervention may be indicated. Late decelerations may indicate poor uterine perfusion or decreased oxygenation. Causes include maternal hypotension caused by inferior vena cava compression, blood loss, or regional anesthesia. Persistent late decelerations warrant investigation to correct the cause and sometimes delivery of the child.

A sinusoidal heart rate pattern is an uncommon baseline abnormality. It has the characteristics of a smooth sine wave with a frequency of 3 to 5 cycles per minute. Variability is minimal (0 to 5 bpm). This pattern has been associated with mild hypoxia in the setting of fetal anemia.⁴²

Fetal Monitoring for Trauma or Surgical Patients

Utility of both FHR and uterine contraction monitoring lies in the ability to intervene based on the acquired information. The most optimal environment for a fetus is optimal maternal physiology. While providing care to the mother, fetal monitoring may assist in improving maternal perfusion and/or oxygenation, may diagnose fetal distress requiring a cesarean section, or may detect uterine contractions that may require tocolytic treatment when the fetus is premature. Depending on the availability of neonatal care, fetal survival is possible starting at around 24 weeks of gestation. The uterus rises above the umbilicus at approximately 20 weeks. Fetal and uterine monitoring is suggested when the gestational age is 20 weeks or beyond. Whenever possible, discussion with the mother or family should occur prior to operation to delineate the expectations regarding fetal survival and quality of life of an extreme premature infant. Consultation with obstetrics or neonatology/pediatrics may be helpful. Intraoperative fetal distress as indicated by an ominous heart rate tracing must be treated by correcting maternal hypotension or increasing oxygen delivery with increased fraction of inspired oxygen (F_{IO_2}), blood transfusion, or more aggressive fluid resuscitation. The inability to improve the intrauterine milieu can necessitate an emergent cesarean section to prevent fetal demise. Even when delivery is not an option because of prematurity, fetal and uterine monitoring may still assist in the management of the mother optimizing the intrauterine environment.

Concern for premature labor may necessitate the use of tocolytic agents. In most cases, indomethacin 50 mg by mouth every 6 hours can be used. When the pregnancy is at high risk for premature delivery, steroid administration prior to operation should be considered (refer to the Preterm Onset of Labor section).

APPENDICITIS IN THE PREGNANT PATIENT

Appendicitis affects 250,000 patients every year in the United States. As a disease of the young, its peak incidence corresponds to the childbearing years. Appendicitis is the most common nonobstetric indication for operation during pregnancy, with an average incidence of 1 in 1,500 deliveries. Although some smaller studies have suggested that this condition is more common later in gestation,⁴²⁻⁴⁴ larger series show an equal distribution throughout pregnancy.⁴⁵ The incidence is similar to that in nonpregnant women, but the anatomic and physiologic changes of the gravid state make the diagnosis difficult.

Classic appendicitis in the nonpregnant patient presents with a constellation of signs and symptoms suggesting the disorder.

Luminal obstruction of the appendiceal orifice, whether by fecalith or lymphoid hyperplasia, leads to an increase in intraluminal pressure by blocking the normal egress of mucus. Progressive obstruction of venous outflow followed by capillary and arterial thrombosis leads to mucosal ulceration, transmural wall necrosis, and, if unabated, perforation. Because early appendiceal distention is relayed by stretch receptors to the 10th thoracic ganglion, referred pain is perceived in the distribution corresponding to the epigastric region. Once the ongoing inflammation extends to involve the parietal peritoneum, the pain localizes to the right lower quadrant. Anorexia, nausea, and vomiting, initiated by visceral mechanisms similar to those responsible for the referred pain, follow the onset of pain. Findings on physical examination arise from this pathophysiologic process. Voluntary guarding of the right lower quadrant reflects the patient's anticipation of pain with palpation in the area. Rigidity or involuntary guarding indicates reflex spasm of the abdominal musculature caused by the nearby inflammatory process, whereas psoas and obturator signs indicate respective irritation of these muscles. Tenderness on rectal examination can be elicited with a low-lying appendix, whereas fever and leukocytosis indicate systemic inflammation. Although none of these signs or symptoms is 100% diagnostic, the presence of right lower quadrant pain, rigidity, and migration of pain was found to have the highest likelihood ratio for the presence of appendicitis in a large multifactorial analysis.⁴⁶ All the aforementioned signs and symptoms are altered by pregnancy (Table 110.4).

In a classic 1932 study, Baer et al.⁴⁷ evaluated the migration of the appendix through the duration of pregnancy with barium enemas. Beginning in the third month of pregnancy, the appendix and cecum are gradually displaced by the uterus and start a craniad migration out of the pelvis into the upper abdomen. By the third trimester, the appendiceal tip can abut the gallbladder (Fig. 110.3). The vague, referred epigastric pain caused by early appendiceal obstruction is not changed by this anatomic consideration, but the location of the somatic pain is. In a large study of pregnant women with proved appendicitis, abdominal pain was present in all patients. Location of pain in the right lower quadrant, however, was common only early in gestation, and a portion of patients reported pain in the right upper quadrant. This change in symptomatology is easily understood if the anatomic changes of the appendix are taken into consideration.⁴⁵ Both guarding and rigidity are valuable findings on physical examination but are common only in the first trimester. Elevation of the abdominal wall from the more laterally placed, upward-directed appendix and the laxity of the abdominal wall musculature caused by this distention decrease the reliability of these findings. Only 42.9% of patients in the third trimester are reported to have abdominal spasm and guarding, compared with 80% during the first trimester.⁴⁸ Psoas and obturator signs are similarly obscured as the appendix is moved from its normal location.

Anorexia, nausea, and vomiting occur in 58% to 77% of pregnant patients with appendicitis.^{45,49} Although nausea and

TABLE 110.4

VARIATION IN SIGNS AND SYMPTOMS OF APPENDICITIS DURING PREGNANCY

■ SIGNS AND SYMPTOMS	■ FIRST TRIMESTER (%)	■ SECOND TRIMESTER (%)	■ THIRD TRIMESTER (%)
Right lower quadrant pain	100	50	14
Right upper quadrant pain	0	17	57
Guarding (muscle spasm)	80	50	43
Nausea and vomiting	53	60	23
Tenderness on rectal examination	60	17	0
Perforation rate	20	49	70

FIGURE 110.3. Changing location of the appendix throughout gestation. (From Baer JL, Reis RA, Arens RA. Appendicitis in pregnancy. *JAMA* 1932;98:1963, with permission.)

vomiting in the first trimester is common, its occurrence during the later stages of pregnancy should raise suspicion. Anorexia, nausea, and vomiting during the second and third trimester, especially if associated with abdominal pain, require a thorough investigation.

The results of laboratory examinations commonly used to assist in the diagnosis of appendicitis are also obscured by pregnancy. The physiologic leukocytosis of pregnancy, ranging from 5,000 to 12,000 WBCs per mL, overlaps that of appendicitis. In one collected series, the WBC counts of pregnant patients with proved appendicitis was not significantly elevated over these values, and only 25% of patients had a WBC count over 15,000. Most patients (50%) had WBC counts ranging between 10,000 and 15,000, and 25% had less than 10,000 WBCs per mL.⁴⁵ Urinalysis is a useful adjunct in the workup of appendicitis but again presents a dilemma in pregnancy. Urinary tract infection is common in pregnancy as the enlarging uterus compresses the right ureter. Dilatation and stagnant flow in the right collecting system can contribute to bacterial overgrowth and infection, and an inflamed and enlarging appendix can contribute to the urinary tract infection by further compressing this system. Pyuria without bacteria can also indicate involvement of the right ureter in the appendiceal inflammatory process. Pus or bacteria in the urine does not rule out appendiceal inflammation, as the two conditions often coexist. Attributing abdominal pain to pyelonephritis and choosing a course of antibiotics rather than further investigation only leads to a delay in diagnosis and missed appendicitis.⁴⁴

These complicating factors and the physician's fear of surgically induced premature labor can contribute to delay of appendectomy in pregnancy. One series documented a correlation between a delay in the diagnosis and gestational age. In the first trimester, all the diagnoses were made promptly and timely surgical intervention undertaken. A delay in diagnosis occurred in 18% of patients presenting in the second trimester, but in the third trimester delay was the rule. Numerous patients were discharged from the emergency room with various misdiagnoses ranging from false labor to nausea and vomiting of pregnancy to gastroenteritis. All presented with vague signs and symptoms obscuring the true diagnosis.⁵⁰ Other series have documented the same delay in operation with a high rate of perforation, as high as 49% in the second trimester and 70% in the

third.^{45,49} Patients with perforated appendicitis usually experienced symptoms more than 24 hours before operation.⁴³

Perforated appendicitis presents a greater infectious risk in the pregnant patient than in the population as a whole. The large uterus interferes with proper omental migration throughout the abdominal cavity and prevents the walling off of the inflammatory process. Braxton Hicks contractions disrupt adhesion formation, and the general increase in vascularity of the abdomen with greater lymphatic drainage allows rapid dissemination of infection. The high circulatory levels of adrenocorticoids in pregnancy have also been hypothesized to diminish the tissue inflammatory response and hinder containment of infection.^{51,52} Perforated appendicitis in pregnancy rapidly leads to diffuse peritonitis, premature labor, and fetal loss. The rate of preterm labor and fetal loss with perforated appendicitis ranges from 26% to 66%, compared with 0% to 5% for uncomplicated appendicitis.^{45,49,53}

Although history and clinical examination for suspected appendicitis during pregnancy are not ideal, they are still the best tools for detecting the disease. A patient with appendicitis during the first trimester might present with right lower quadrant pain, guarding, and nausea and vomiting, whereas a woman in the third trimester would most likely have pain in another location and a more confusing clinical picture. The adage "If you cannot rule it out, take it out" applies in pregnancy as well as the nongravid state.⁴⁵ In applying this principle, the average negative laparotomy rate is 19% to 35% in the pregnant patient, a rate similar to that in the population as a whole.⁵⁴ Negative laparotomy rates as high as 75% in the third trimester, however, have been reported.⁵⁵ Although complication rates are low for negative explorations, fetal loss does occur. Imaging studies offer the potential of increasing the accuracy of the diagnosis of appendicitis.

Imaging Modalities

Ultrasonography is safe for the developing fetus and the study of choice in the pregnant patient. Findings that suggest appendicitis include visualization of a tubular structure with a diameter greater than 6.0 mm, a wall thickness above 3.0 mm,⁵⁵ and

FIGURE 110.4. Ultrasonographic appearance of appendicitis. The appendix appears as a thick, noncompressible tubular structure with central hypoechoogenicity. The walls are 5 mm thick, over the 3-mm limit for a normal appendix. (Courtesy of Dr. Beverly Coleman, Department of Radiology, Hospital of the University of Pennsylvania, Philadelphia, PA.)

lack of peristalsis (Fig. 110.4). Because a normal appendix is difficult to identify, simply seeing the appendix combined with tenderness on palpation with the ultrasound probe is suggestive of appendicitis. Ultrasonography, however, has been criticized for being operator dependent and situation specific. Sensitivity varies widely, from 68% to 89%,^{48,56} and examination can be prohibitive because of abdominal guarding, pain during examination, and a thick abdominal wall. Distortion of anatomic landmarks and the displacement of the appendix by the gravid uterus complicate the diagnosis. Other structures such as an inflamed salpinx can also mimic appendicitis on ultrasound,⁵⁷ and a dilated uterine vein during pregnancy has been mistaken for an acutely inflamed appendix.⁵⁶ Despite these limitations, ultrasound is readily available in the emergency department or office and often can add diagnostic information to a confusing clinical picture. If the patient's history and physical examination do not warrant an immediate operation, abdominal ultrasonography should be the first study obtained.

Computed tomography (CT) has emerged as a highly reliable modality in the diagnosis of appendicitis. Appendiceal CT, using rectally administered contrast, can be performed within 10 to 20 minutes, does not require a waiting period for oral contrast to progress down through the cecum, and exposes the patient to only one third the radiation of a regular CT scan.⁵⁸ Results at one center⁵⁹ have indicated that CT interpretation can be 98% sensitive and 98% specific for the diagnosis of appendicitis. Routine use of this modality reduces costs, expedites the diagnosis, and reduces perforation rates from 22% to 14% while decreasing the incidence of negative laparotomy from 20% to 7%.^{59,60} Although radiation risks to the developing fetus do exist, it is unlikely that fetal loss or malformations occur with the dosing needed for an abdominal CT. Because even low levels of radiation in utero can increase the incidence of childhood cancer, widespread use of this modality in the pregnant patient with abdominal pain may be detrimental. Reserving the CT scan for those cases where the clinical history, physical examination, and ultrasonography are indeterminate should decrease the rate of perforation and negative exploration, just as it has in the nonpregnant population (Fig. 110.5).

FIGURE 110.5. Computed tomography (CT) scan of a woman in the 18th week of gestation presenting with a 12-hour history of right-sided abdominal pain. Abdominal examination on presentation revealed significant tenderness; after a nondiagnostic ultrasound, a laparotomy is considered for presumed appendicitis. A CT scan is obtained instead, revealing a normal, air-filled appendix with no sign of periappendiceal inflammation (arrow). The laparotomy was postponed, and 12 hours later the patient aborted a septic fetus. An unnecessary laparotomy for an atypical presentation of chorioamnionitis was avoided by the judicious use of the CT scan. (Courtesy of Dr. David Weiss, Chestnut Hill Hospital, University of Pennsylvania Health System, Chestnut Hill, PA.)

MRI uses no ionizing radiation and, like CT, has the potential to image the whole abdomen. It is generally considered safe in pregnancy, and initial experimentation has shown that the higher water content of an inflamed appendix can be detected by MRI.⁶¹ Reported sensitivity for appendicitis approaches 100%, at least in children.⁶² Routine use of MRI may be hindered by availability and limited experience for detecting appendicitis using this modality. Future studies of MRI in appendicitis are warranted.

Laparoscopy

Pregnancy is no longer a contraindication to laparoscopy. Although earlier studies reported a high rate of fetal and maternal complications, it is likely the underlying pathologic process rather than laparoscopy contributed to maternal morbidity and fetal demise.⁶³ Fetal acidosis with experimental maternal CO₂ pneumoperitoneum has been reported but can be minimized in the clinical setting with arterial blood gas monitoring and careful attention to maternal ventilation and acid-base balance.⁶⁴ Concerns regarding the effect of increased intra-abdominal pressure are questionable considering the high uterine pressures during delivery. Experimental pneumoperitoneum in itself does not alter hemodynamics in the fetus until pressures of 20 torr are reached.⁶⁴ Reduced insufflation pressures of 8 to 12 mm Hg should not contribute to fetal morbidity and mortality. Patients undergoing nongynecologic laparoscopic surgery begin a regular diet sooner, have lower narcotic requirements, and are discharged from the hospital earlier than patients undergoing open surgery.⁶⁵

Laparoscopy to evaluate the appendix is a feasible diagnostic modality during pregnancy but may be difficult during later gestation. Anatomic changes alter placement of trocars above the gravid uterus⁶⁶ and require the use of the open Hasson technique of trocar placement under direct visualization rather than blind insufflation with a Veress needle. Maneuvers to enhance operative safety of laparoscopy in pregnancy have been outlined by the Society of American Gastrointestinal and Endoscopic Surgeons⁶⁷ (Table 110.5).

TABLE 110.5**GUIDELINES FOR LAPAROSCOPIC SURGERY DURING PREGNANCY**

1. Defer operative intervention until the second trimester, when the fetal risk is lowest, whenever possible.
2. Pneumatic compression devices must be used because of the enhancement of lower venous stasis with pneumoperitoneum and pregnancy-induced hypercoagulable state.
3. Fetal and uterine status, as well as maternal end-tidal CO₂ and arterial blood gases, should be monitored.
4. Use fluoroscopy selectively and protect the uterus with lead shield if intraoperative cholangiography is possible.
5. Given enlarged gravid uterus, abdominal access should be obtained using open technique.
6. Dependent positioning should be used to shift the uterus off the inferior vena cava.
7. Pneumoperitoneum pressures should be minimized (to 8–12 mm Hg) and not allowed to exceed 15 mm Hg.
8. Obstetric consultation should be obtained before operation.

From SAGES Committee on Standard Practice. Guidelines for laparoscopic surgery during pregnancy. *Surg Endosc* 1998;12: 189–190.

Appendectomy

Once the diagnosis of appendicitis is made, treatment is strictly surgical. The type of incision can vary based on surgeon preference but becomes an issue during later pregnancy. Because of the migration of the appendix, an incision over the McBurney point in the late second and third trimester is inadequate. A low midline incision is favored by some to allow treatment of other conditions that mimic appendicitis but may require excessive retraction of the uterus.⁵⁰ A right-sided transverse incision over the point of maximal tenderness is usually the safest approach because the appendix typically lies beneath that point.^{43,45,49} A similar incision at the level of the umbilicus allows good exposure of most of the right upper and lower abdomen. By tilting the patient 30 degrees to the left, the uterus is shifted away from the operative field and off of the inferior vena cava. A right paramedian incision usually necessitates medial retraction of the uterus for exposure and increases the risk of precipitating premature labor. The laparoscopic approach, although useful for both diagnosis and treatment, can be difficult in later gestation. While the potential benefits over the open appendectomy include less uterine manipulation and decreased incidence of preterm labor, its utility depends heavily on surgeon experience and comfort with the procedure.^{65,66}

If exploration reveals a normal appendix, an appendectomy still should be performed. Although some authors question this approach because of the suggested high rate of preterm labor with a normal appendectomy,⁶⁸ most believe this to be untrue. Taking out the normal appendix adds little to morbidity while eliminating potential confusion if symptoms should recur.⁴⁵ Perforated appendicitis or pus in the abdominal cavity demands thorough peritoneal toilet along with the appendectomy. Drainage of the perforated appendectomy bed was avoided in the past because of fears that foreign material increased the risk of premature labor,⁴⁷ but these fears have not been substantiated and drainage of the appendiceal stump has been performed without complications.

BILIARY TRACT DISEASE IN PREGNANCY

Acute cholecystitis is the second most common general surgery diagnosis during pregnancy. Progesterone-induced relaxation of the gallbladder combined with estrogen-induced supersaturation of bile predispose to gallstone formation.^{38,69} The risk for development of gallstones is related to the number of pregnancies, doubling after two pregnancies and nearly quadrupling after four.^{69–71} Although gallstones are found in approximately 4% of all pregnant patients undergoing routine ultrasonography early during pregnancy, the rate can be as high as 12.2% immediately after delivery in high-risk populations.⁷⁰ Despite this high prevalence of gallstones, the incidence of acute cholecystitis during pregnancy is relatively low—1 to 8 in 10,000 pregnancies (0.01% to 0.08%).^{72,73} Inhibition of gallbladder contraction by progesterone is most likely the reason for this discrepancy. Although gallstones and sludge can form, weaker contractions prevent cystic duct obstruction until delivery. Postpartum, the progesterone concentrations decrease and the increased force of gallbladder contraction potentiates gallstone-induced cystic duct obstruction. An increased prevalence of cholecystitis in the year after childbirth has been noted.^{74–76}

Symptoms of cholecystitis or biliary colic caused by cystic duct obstruction are similar in the pregnant and nonpregnant patient. Crampy right upper quadrant or epigastric pain after a meal can last several minutes to hours. The pain may radiate to the back and accompany nausea and vomiting. Tenderness on palpation of the right upper quadrant is usually present with acute cholecystitis, but laboratory evaluation may be obscured by the normal leukocytosis and elevated alkaline phosphatase during pregnancy. Increased bilirubin or visible jaundice, however, is unlikely without common bile duct obstruction.⁷³

The differential diagnosis for cholecystitis during pregnancy includes hepatitis, acute fatty liver of pregnancy, and appendicitis. The diagnosis can be strengthened by the history and physical examination and confirmed by abdominal ultrasound. Ultrasonography is more than 97% accurate in detecting cholecystitis, with typical findings of echogenic shadowing, gallbladder wall thickening, and pericholecystic fluid.⁷⁷ Pain on palpation with the ultrasound transducer, or a sonographic Murphy sign, is confirmatory of inflammation.

Historically, medical management was the definitive treatment of cholecystitis during pregnancy. The pregnant patient was given nothing orally, maintained on intravenous hydration, and treated with antibiotics for signs of infection. A low-fat diet was started once symptoms abated, antibiotics were discontinued, and the patient was discharged to home. Most women had initial relief of symptoms with this management, and surgery was reserved for those with persistent symptoms, severe toxicity, sepsis, peritonitis, or obstructive jaundice.⁷⁸ Fear of surgical complications prompted some to place pregnant patients with disabling biliary symptoms on total parenteral nutrition until delivery.^{65,79} Analysis of patient outcomes throughout the course of pregnancy, however, has put strict medical management into question. Between 57% and 70% of patients treated for gallstone disease during pregnancy have recurrence at some time during gestation.^{80,81} This risk is close to 92% for those who present in the first trimester, 64% for those presenting during the second trimester, and 44% for those who present during the third. Of these patients, 90% require hospitalization for management of the relapse,⁸⁰ and a significant portion of those presenting in the first trimester experience pregnancy loss as a complication of the disease.^{79,82} Complications of gallstones such as choledocholithiasis and pancreatitis can also arise with future attacks and have been

associated with a maternal mortality rate of 15% and a 60% chance of fetal demise.^{78,83-85}

- 5** Laparoscopic cholecystectomy is a safe and reliable modality to treat gallstone disease during pregnancy. Numerous reports and case control studies comparing laparoscopic with open cholecystectomy have supported the laparoscopic approach. Overall, patients have a shorter postoperative stay, resume oral intake earlier, have fewer postoperative hernias, and experience less pain with lower narcotic requirements by avoiding a large open incision.^{63,65,86} Because fetal loss is most likely related to the underlying maternal illness and extent of uterine manipulation during surgery,^{81,87} laparoscopic cholecystectomy offers a solution to both problems. Removing the diseased gallbladder eliminates the potential for recurrence, and the minimal uterine retraction needed with laparoscopic access to the right upper quadrant should decrease the risk for preterm labor. Although no randomized studies exist, preliminary data seem to support these assumptions. The incidence of premature uterine contractions with laparoscopic cholecystectomy has been reported at 0% to 21%, but contractions are usually well controlled by tocolytics. Most series report rates of premature birth or spontaneous abortion ranging from 0% to 7% with the laparoscopic approach.^{66,80,81,87} After an open cholecystectomy, the reported rate of premature labor ranges from 0% to 40%, based on trimester,⁸⁸ and a spontaneous abortion or premature birth rate of up to 22% has been reported.⁷ Based on the available data, laparoscopic cholecystectomy is safe during pregnancy and is preferable to open cholecystectomy.⁸⁸ An isolated report of three laparoscopic cholecystectomies ending in abortion, however, has been published, emphasizing that this procedure is not without risk, so careful attention must be paid to the timing, indications, and maternal physiology before any procedure.⁸⁹

Because most biliary symptoms can be controlled, at least initially, with conservative management, the management of symptomatic gallstones varies based on the stage of gestation. The second trimester is the optimal time to perform an elective cholecystectomy. Organogenesis is complete, and the gravid uterus is not yet large enough to impinge on the operating field.⁸⁵ Clinical studies of open cholecystectomy confirm that this is the safest time to perform the operation. Spontaneous abortion rates after an open cholecystectomy are 12% during the first trimester, whereas the incidence of premature labor can be as high as 40% during the third trimester. The second trimester offers the ideal compromise, with the low spontaneous abortion rate of 5.6%.⁸⁸ Laparoscopic cholecystectomy offers the potential to decrease fetal loss even further over these values. Suggested management for symptomatic cholelithiasis during the first trimester consists of conservative measures until elective cholecystectomy can be performed safely during the second trimester of gestation. Second trimester disease can be dealt with surgically, whereas those presenting later in gestation can probably be managed symptomatically until the postpartum period. If symptoms are unremitting and cannot be handled with diet alone, surgical intervention might be necessary regardless of the period of gestation.^{76,81}

FHR monitoring is an essential part of laparoscopic procedures. Because pneumoperitoneum can have detrimental physiologic effects on both the mother and fetus, any evidence of fetal distress should result in immediate desufflation.⁶⁷ FHR aberrations can also be treated by increasing uterine perfusion with maternal intravascular volume and changing the mother's position on the operating room table to decrease uterine compression of the inferior vena cava. Because the transabdominal signal is lost with pneumoperitoneum, transvaginal monitoring should be used during surgery,⁶⁵ whereas an external tocodynamometer should be placed on the abdomen immediately after the completion of the operation to monitor for uterine contractions. Tocolytic agents need not be used prophylacti-

cally but can be administered if the patient demonstrates uterine irritability or contractions. The rate of successful tocolysis after laparoscopic procedures with minimal uterine manipulation is close to 100%.^{63,65,76,83,87,90}

Choledocholithiasis

Indications for evaluation of the common bile duct are no different in the pregnant patient from the population as a whole, namely a bilirubin above 1.5 mg/dL, a dilated common bile duct, or gallstone pancreatitis.⁶⁶ Endoscopic retrograde cholangiopancreatography (ERCP) can be performed safely in pregnancy. With proper lead shielding, judicious use of fluoroscopy time, and avoidance of permanent roentgenographic films, ERCP has been performed with no direct exposure of the fetus to radiation. Calculated scatter radiation on the order of 4 mrad during the whole examination presents the only risk from ionizing radiation.⁸⁴ Evaluation of the biliary tree, stone retrieval, and sphincterotomy can be performed under these conditions without maternal or fetal complications.⁹¹ Other methods avoid radiation altogether and include imaging of choledocholithiasis with endoscopic ultrasonography,⁹² endoscopic papillotomy under ultrasonographic control,⁹³ and magnetic resonance cholangiography for choledocholithiasis.⁹⁴ Success with all these modalities has been reported but can be limited by operator experience and availability.

INTESTINAL OBSTRUCTION DURING PREGNANCY

The incidence of intestinal obstruction during pregnancy rose throughout the 20th century. In the presurgical era, cases were cited as infrequently as 1 in every 68,000 deliveries. Since the 1940s, however, the incidence has increased to 1 in 2,500 to 3,500 deliveries.⁹⁵ This change reflects the increased number of laparotomies in young women and the prevalence of postoperative adhesions during pregnancy. Adhesions remain the most common cause of intestinal obstruction in the gravid patient, but intestinal volvulus is a much more common complication than in the population as a whole. Intussusception, hernia, and carcinoma are responsible for a minority of cases of bowel obstruction (Table 110.6).

TABLE 110.6

CAUSES OF INTESTINAL OBSTRUCTION COMPLICATING PREGNANCY AND THE PUERPERIUM IN 66 PATIENTS

Adhesions	39 (59%)
Volvulus	15 (23%)
Sigmoid	7
Cecal	3
Midgut	3
Volvulus around vitellointestinal band	2
Intussusception	3 (5%)
Hernia	2 (3%)
Carcinoma	1 (1%)
Appendicitis	1 (1%)
Idiopathic (ileus)	5 (8%)

From Perdue PW, Johnson HW, Stafford PW, et al. Intestinal obstruction complicating pregnancy. *Am J Surg* 1992;164:385.

Obstruction during pregnancy classically presents during three peak periods because of the change in the interrelationship between the abdominal viscera caused by the gravid uterus. The first peak occurs during the fourth to fifth months of gestation as the uterus becomes an intra-abdominal organ, stretching any previously formed adhesions. The second peak occurs during the eighth to ninth months, when the fetal head descends into the pelvis, decreasing the uterine size. The third peak occurs after delivery as the sudden decrease in uterine size drastically changes the association of adhesions to surrounding bowel. The incidence of adhesion-related obstruction is highest during the first pregnancy after an operation, when the association between the viscera and adhesions is initially tested.^{89,95}

In the general population, incarceration of bowel in groin hernias is the second most common cause of small bowel obstruction, but in the pregnant patient volvulus becomes the number two cause. As the enlarging uterus displaces the bowel out of the pelvis and away from the inguinal region, symptomatic groin hernias diminish in frequency.⁹⁶ Volvulus increases in prevalence during pregnancy because of changes in colon and small bowel anatomy and causes one fourth of all bowel obstructions. Sigmoid volvulus normally occurs owing to a long and redundant sigmoid colon. In the United States, this usually occurs in debilitated, institutionalized, or chronically constipated people. In countries such as Africa, a high incidence of sigmoid volvulus has been attributed to the high-fiber vegetable diet characteristic of that population. Anatomic changes of pregnancy further exacerbate this condition by causing the redundant sigmoid colon to rise out of the pelvis and twist around its point of fixation.⁹⁷ It is the most common site of volvulus during pregnancy.⁹⁸

Cecal volvulus occurs because of failure of lateral peritoneal fixation during development. As the uterus enlarges during pregnancy, it raises the redundant or abnormally mobile cecum out of the pelvis. If a transition point or distal obstruction should occur from uterine pressure or an adhesive band, the colonic distention raises the colon even higher, producing torsion around this fixed point.⁹⁹ Volvulus of the small bowel also results from a congenital abnormality of rotation and fixation. Because clinical presentation usually occurs in infancy or childhood, the true incidence of malrotation in adulthood is unknown. The enlarging uterus potentially predisposes to the presentation of this anomaly during pregnancy by pushing the nonfixed, mobile portions of the small bowel into the upper abdomen, initiating the volvulus.¹⁰⁰

Presentation and Diagnosis

Symptoms of intestinal obstruction are similar to those in the nonpregnant patient and commonly include abdominal pain and vomiting. Proximal small bowel obstruction results in short periods between vomiting episodes with poorly localized, crampy upper abdominal pain. Colonic obstruction can present with less frequent feculent vomiting and lower abdominal pain. Findings on physical examination such as abdominal distention are often difficult to evaluate because of the gravid uterus. Obstipation, although characteristic of distal obstruction such as sigmoid volvulus, may not occur with proximal obstruction. Laboratory studies, although useful to rule out other conditions, are not reliable enough to be considered diagnostic of obstruction. Significant leukocytosis can occur with necrosis and bowel strangulation, but mild elevations are not definitive because of the physiologic leukocytosis of pregnancy. Tachycardia and hypotension are also late signs suggesting bowel compromise and shock.

The murky clinical picture combined with the tendency to treat the progressive vomiting as a normal part of pregnancy and crampy abdominal pain as early contractions lead to a

delay in presentation and diagnosis. The median time from the onset of symptoms to admission in one series was 48 hours, and the median time from admission to a necessary laparotomy was also 48 hours. This delay in diagnosis and treatment contributed to excessive maternal and fetal mortality.⁹⁶ Abdominal pain and vomiting in a pregnant patient with an abdominal scar should raise the serious suspicion of small bowel obstruction.

If intestinal obstruction is suspected, upright and flat films of the abdomen are the diagnostic studies of choice. Although some authors⁹⁵ believe that radiographs are nonspecific early in obstruction, serial films obtained every 4 to 6 hours usually show progressive changes confirming the diagnosis. Small bowel obstruction gives the appearance of a progressive stepladder formation with dilatation and multiple air-fluid levels. Large bowel obstruction can produce a similar picture or reveal a grossly dilated bowel loop suggestive of volvulus. Contrast studies are also useful, and a "bird's bill" shape of contrast with gradual narrowing after a barium enema can be diagnostic of colonic volvulus, whereas dilute diatrizoate (Gastrografin) or barium by mouth can usually differentiate partial from complete obstruction. Fetal radiation risks from the plain radiographs are negligible and greatly outweighed by those from the possibility of misdiagnosis.

Treatment

The initial treatment for bowel obstruction in the pregnant patient is no different from that of a nonpregnant patient. Nasogastric tube decompression and fluid resuscitation are the cornerstones of therapy. By the time an obstruction is visible on plain film, the fluid deficit from vomiting and intraluminal losses is estimated at 1,000 to 1,500 mL. In advanced cases of dehydration presenting with tachycardia and hypotension, fluid losses may be as high as 4 to 6 L.⁹⁵ Prompt fluid resuscitation is essential in the pregnant patient because compromise of uterine blood flow leads to fetal distress and demise.

Surgical intervention plays a prominent and earlier role in the management of the pregnant patient with bowel obstruction. Although adhesion-related small bowel obstruction in the nonpregnant patient usually resolves with nasogastric decompression and fluid administration, numerous series have documented failure of conservative management of small bowel obstruction in the pregnant woman. Of all patients, 89% to 100% eventually require an operation, and 13% to 23% require resection of gangrenous bowel at the time of laparotomy.^{96,101} Based on these outcomes, some have stated that once the diagnosis of small bowel obstruction is made in a pregnant patient, the only role of nasogastric decompression and fluid resuscitation is to prepare the patient for an operation.¹⁰¹ Cecal volvulus is also treated surgically, and although sigmoid volvulus in the nonpregnant patient can be managed with sigmoidoscopic decompression and placement of a rectal tube, the large gravid uterus may act as a mechanical impediment to detorsion. A laparotomy is usually necessary for treatment.^{96,97}

A generous midline incision allows for maximum exposure of the abdomen with minimal manipulation of the uterus. During lysis of small bowel adhesions, bowel viability must be carefully assessed. Definitive management of cecal volvulus requires resection of necrotic cecum or detorsion and cecopexy. Sigmoid volvulus should also be treated by resection if necrotic, but simple detorsion and placement of a rectal tube can be performed if the sigmoid is viable. Although resection of the redundant sigmoid is the definitive treatment for this disease, it can be delayed until the postpartum period. Aggressive surgical treatment has been credited with reducing the maternal and fetal mortality rates from 20% and 50%, respectively, in the 1930s to 6% and 26% today.⁹⁶ Increased awareness of this

disease and expeditious management can reduce those rates even further.

COLORECTAL CANCER DURING PREGNANCY

Colon cancer is a rare disease during pregnancy but one with lethal consequences. The incidence of colon cancer was estimated as 1 in 50,000 pregnancies based on a 1955 report.¹⁰² More recent reviews estimate the incidence as 1 in 13,000 deliveries,¹⁰³ with the increasing prevalence attributable to increasing maternal age with the delay in pregnancy until later in life.¹⁰⁴ Presenting symptoms are similar to those in non-pregnant patients and include rectal bleeding, constipation, and abdominal pain and distention as well as nausea and vomiting.¹⁰⁵ All of these symptoms are common during pregnancy. Even the findings of occult blood in the stool and hematochezia are often attributed to pregnancy-related hemorrhoids and ignored.

The anatomic distribution and stage of colorectal cancer in the pregnant patient differ from those in the population as a whole. A nationwide survey of the members of the American Society of Colon and Rectal Surgeons who had cared for pregnant patients with colorectal cancer revealed a predominance of rectal cancer in this patient population. Of tumors, 64% were distributed below the peritoneal reflection and 36% were in the more proximal colon. A review of more than 200 pregnancy-associated colorectal cancers reported in the literature disclosed a similar distribution with 86% of tumors located in the rectum and only 14% above the peritoneal reflection.¹⁰⁶ This is in contrast to the general population, where most tumors (69%) are located in the colon and only 31% in the rectum. This trend could reflect a presentation bias because of frequent rectal examinations during prenatal care or the change in pelvic anatomy and symptoms of rectal compression by the gravid uterus.

Pregnant patients present with more advanced cancers than the population as a whole. In the study mentioned previously,¹⁰⁶ no pregnant patient was Dukes stage A at presentation, whereas 41% were Dukes stage B, 44% were stage C, and 15% were stage D. Although increased hormonal stimulation during pregnancy could cause rapid tumor growth and progression of disease,^{106–108} not all colon cancers have estrogen or progesterone receptors and respond to this stimulation.¹⁰⁹ The advanced stage of disease on presentation most likely results from a delay in the diagnosis and the low clinical suspicion of malignancy in this patient population. This trend is similar to that in the young population as a whole, and

although only 4% to 8% of all colon cancer occurs in those younger than 40 years, these patients also have a delayed presentation with more advanced disease.¹¹⁰ The average interval between the onset of symptoms and diagnosis of colon cancer in those younger than 40 years is 6.4 months, and 32% of patients wait longer than 1 year before seeking medical attention for symptoms.¹¹¹ The stage of disease on presentation in this patient population is similar to that in the pregnant patient (Table 110.7), and colonic malignancy during gestation most likely represents pregnancy superimposed on colon cancer rather than a pregnancy-related disease.

Diagnosis

Diagnosis of colorectal cancer during pregnancy demands a very high level of suspicion. Patients with rectal bleeding, occult blood–positive stools, and anemia below physiologic levels of pregnancy should be evaluated for a colonic malignancy. Sigmoidoscopy is not contraindicated during pregnancy and does not appear to induce labor or congenital malformations. Because most cancers are located below the peritoneal reflection, they can be easily accessed and sampled for biopsy through a limited sigmoidoscopic examination. Because of the 5% risk of a second, synchronous primary, a more extensive colonoscopic evaluation might be necessary, especially if findings were to change the treatment or extent of surgical resection. Colonoscopy during pregnancy is still considered experimental and may be technically difficult because of colonic compression by the gravid uterus. Maneuvers to increase safety include use of only gentle pressure when manipulating the colonoscope, maternal administration of supplemental oxygen, and FHR monitoring during the procedure.¹¹²

Transrectal ultrasonographic staging of rectal cancer is particularly helpful during pregnancy because of its ability to evaluate cancerous invasion of the uterus or encroachment on the cervix that could prevent vaginal delivery.¹¹² Serum carcinoembryonic antigen levels are not normally elevated during pregnancy, and although of limited use as a screening tool, levels can be obtained before resection for early detection of recurrence.¹¹³ Evaluation of metastatic disease to the liver can be performed with transabdominal ultrasonography at no risk to the fetus, and a CT scan can be obtained in more difficult cases.

Treatment

Treatment of colorectal cancer during pregnancy presents as an ethical dilemma for both the patient and the physician.

TABLE 110.7

STAGE AT PRESENTATION OF COLORECTAL CANCER DURING PREGNANCY AND THOSE YOUNGER THAN 40 YEARS OF AGE

■ DUKES STAGE	■ PREGNANT PATIENTS (%)	■ PATIENTS <40 Y (%)
A	0	2
B	41	30
C	44	45
D	15	23

Data from Bernstein MA, Madoff RD, Caushaj PF. Colon and rectal cancer in pregnancy. *Dis Colon Rectum* 1993;36:172–178; Smith C, Butler JA. Colorectal cancer in patients younger than 40 years of age. *Dis Colon Rectum* 1989;32:843–846.)

Aside from the difficulty in dealing with a potentially lethal disease in a young person, there is an inherent conflict between the treatment of the mother and fetus. Treatment of other surgical conditions encountered during pregnancy, such as appendicitis or cholecystitis, equally benefits both the mother and the unborn child. Treatment of colon cancer puts the two at odds. Although early tumor resection can improve the prognosis for the mother, this treatment might be detrimental to the fetus. Adjuvant chemotherapy or radiation therapy can improve survival of the mother but is generally contraindicated during pregnancy, especially early in gestation. Careful attention must be paid to the wishes of the family while explaining the risks and benefits for both the mother and child.

If the cancer is discovered in the first half of gestation, a definitive resection should be performed. Waiting months until adequate fetal maturation for delivery can allow cancer dissemination and disease progression.^{105,112} In most cases, a colon resection can be handled without disturbing the pregnancy, and resection of even low-lying tumors can be performed before 20 weeks of gestation.^{109,113} Total abdominal hysterectomy is recommended only if tumor invasion into the uterus has occurred, a technically complete operation cannot be performed without it, or the mother's life expectancy is shorter than the time needed to reach fetal viability. If the tumor is unresectable, a colostomy is performed for palliation until fetal viability is documented.

Treatment of tumors discovered after the 20th week can be postponed until term or fetal viability. Vaginal delivery is not contraindicated unless the tumor is obstructing the birth canal or presents a risk of episiotomy entering the tumor bed. Tumor resection is undertaken several days after the birth to allow uterine involution and resolution of pelvic vascular congestion. If a cesarean section is performed for obstetric reasons or because of tumor impingement on the birth canal, resection can be performed immediately, but the operation may be technically easier if done as a separate procedure and postponed for several days. This is especially important with low rectal lesions, where decreased pelvic vasculature can facilitate a low anterior or abdominoperineal resection.¹⁰⁵

Management of the ovaries is a controversial issue. The incidence of colon carcinoma metastasizing to the ovaries is estimated to be between 3% and 8%¹¹⁴ in the general population but can be as high as 25% during pregnancy and in young patients.^{111,115} Bilateral salpingo-oophorectomy at the time of tumor resection has been advocated by some,¹¹⁴ but during pregnancy the procedure carries a high chance of spontaneous abortion, especially during the first half of gestation. Although resection should be performed if the ovaries are grossly involved with tumor or a hysterectomy is undertaken, bilateral ovarian wedge biopsies with frozen section evaluation can be safely carried out without disturbing the pregnancy. Salpingo-oophorectomy is then performed only if the ovaries are involved with tumor.¹⁰⁵

Adjuvant chemotherapy conveys a survival advantage to patients with Dukes stage C colon cancer. The classic adjuvant chemotherapy includes 5-fluorouracil, an antimetabolite that inhibits DNA synthesis. The safety of this drug during pregnancy is questionable, and evidence of fetal toxicity exists in animal models. Limited data on the human fetal safety of this drug are available, and it is considered a category D drug during pregnancy by the FDA: generally unsafe during pregnancy, but the risk may be justifiable in certain circumstances. Chemotherapy during the first trimester is usually contraindicated and should be limited to those patients with Dukes stage C lesions who may choose to accept the risks of fetal teratogenesis or demise. Chemotherapy during the second and third trimesters is less teratogenic because of the completion of organogenesis but still carries some risk for the fetus.^{112,116}

Adjuvant radiation therapy reduces the local recurrence of rectal cancer. Because the most effective dose to eradicate microscopic disease is on the order of 50 Gy and the fetus can-

not be effectively shielded from pelvic exposure, radiation therapy cannot be safely performed during pregnancy. Therapeutic pelvic radiation also results in permanent and irreversible female sterility, so the mother considering this form of therapy must be fully aware of the risks to the current and future pregnancies.^{112,117}

CHAPTER 111 ■ CUTANEOUS NEOPLASMS

MICHAEL S. SABEL, TIMOTHY M. JOHNSON, AND CHRISTOPHER K. BICHAKJIAN

KEY POINTS

- 1 Cutaneous neoplasms are the most commonly diagnosed malignant tumors in the United States, with an incidence of approximately 1.4 million new cases annually.
- 2 Risk factors for development of cutaneous melanoma include ultraviolet (UV) light exposure, fair complexion/inability to tan, blue or green eyes, blonde or red hair, freckling, history of actinic keratosis or nonmelanoma skin cancer (NMSC), history of blistering or peeling sunburns, immunosuppression, personal or family history of melanoma, CDKN2A/p16/MC1R mutation, xeroderma pigmentosa, atypical (dysplastic) nevus, more than 100 normal nevi, and giant congenital melanocytic nevus.
- 3 The ABCD rule is used to assess skin lesions for melanoma risk: A is for *asymmetry*; B is *border irregularity*; C is *color*, and D is *diameter greater than 6 mm*.
- 4 Melanoma prognosis is inverse correlated to tumor thickness; ulceration and increased mitotic rate are independent survival risk factors; and nodal tumor burden (uninvolved vs. microscopic vs. macroscopic disease) has an inverse correlation with survival.
- 5 For melanoma in situ, excision margins of 0.5 to 1.0 cm are indicated; for invasive melanoma, wide excision of the primary tumor with margins generally ranging from 1 to 2 cm is indicated for local control.
- 6 Clinically involved lymph nodes should be resected; patients with primary melanomas of 1 mm thickness or greater and clinically negative nodes should be considered for sentinel lymph node biopsy.
- 7 Basal cell and squamous cell skin carcinoma account for 96% of new NMSCs.
- 8 Dermatofibrosarcoma protuberans (DFSP) is a rare soft tissue sarcoma (1% of all soft tissue sarcomas) with a propensity for local recurrence rather than systemic metastasis.

- 1 Cutaneous neoplasms are the most commonly diagnosed malignant tumors in the United States, with an incidence of approximately 1.4 million new cases annually.^{1,2} One in five Americans born today will be diagnosed with skin cancer in their lifetime. More than half of all cancers diagnosed in the United States are skin cancers. The most common skin cancer types are basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). Cutaneous melanoma accounts for 4% of skin cancer diagnoses but accounts for 75% of skin cancer deaths, with 8,420 deaths due to melanoma in 2008, or about one every hour. Approximately 62,480 new cases of invasive melanoma were diagnosed in the United States in 2008 (34,950 men and 27,530 women). The incidence of melanoma has dramatically increased, with the lifetime risk of melanoma increasing from 1 in 600 in the 1960s to 1 in 41 in men and 1 in 61 in women in 2008.¹ Invasive melanoma is the sixth most common cancer in men and the seventh most common cancer in women.¹ The early diagnosis and surgical treatment of these skin cancers can be curative.

MELANOMA

Etiology and Risk Factors

Numerous environmental and genetic risk factors have been implicated in the development of cutaneous melanoma, many of which center around sun exposure.² Risk factors include factors related to exposure to UVA and UVB, such as geography, occupation, a history of blistering or peeling sunburns, and the use of tanning beds/salons, as well as factors related to increased sensitivity to UV light, such as decreased pigmentation, a fair complexion (blue or green eyes, blonde hair, freckling), or xeroderma pigmentosa. Melanoma incidence is subject to large geographic and ethnic variations, mainly because of an inverse correlation with latitude and with degree of skin

pigmentation. Populations residing closer to the equator have a higher incidence of melanoma. Many factors that increase risk for melanoma are surrogates for a history of excess sun exposure, such as actinic keratosis, a history of either melanoma or an NMSC, atypical nevi, or multiple normal nevi. Finally, there are inheritable risk factors, such as a family history of melanoma, CDKN2A/p16/MC1R mutation, or MC1R mutation.

Adults with more than 100 clinically normal-appearing nevi, children with more than 50 clinically normal-appearing nevi, and any patient with atypical or dysplastic nevi are at risk. A prior history of melanoma places a patient at increased risk, with 5% to 10% of individuals developing a second primary melanoma. This risk of developing a second primary is lifelong and can occur anywhere on the skin. Therefore, long-term surveillance with a thorough total body examination is recommended.

A genetic component has been implicated in the pathogenesis of melanoma. Of patients with melanoma, 10% to 15% report a positive family history. The most common chromosomal mutation associated with melanoma involves CDKN2A, also known as p16. However, the mutation accounts for only a small percentage of melanoma cases observed, estimated at 0.2%. A MC1R gene mutation is clearly a risk factor for cutaneous melanoma.³ The combination of MC1R mutation and red hair is associated with a very high risk of melanoma development. In addition, MC1R R151 C modifies the effect of another cutaneous melanoma susceptibility gene, CDKN2A.⁴ The genetic etiology of melanoma represents an area of future discovery.

The hereditary nature of cutaneous melanoma was also noted in the 1970s.⁵ Members afflicted with the “B-K mole syndrome,” named after two families, acquired large, irregular, and dysplastic nevi, often in sun-protected regions of the body such as the scalp and trunk. During this time period, Lynch et al.⁶ independently reported a familial association of melanoma

among individuals with atypical nevi, which he termed *familial atypical multiple mole melanoma syndrome*, or FAMMM syndrome, with an autosomal dominant inheritance pattern. The 10-year melanoma risk in the setting of atypical mole syndrome is reported to be 10.7% compared with 0.62% in control patients. Greene et al.⁷ approximated a 56% cumulative risk from age 20 to 59 years, with 100% of atypical mole syndrome patients developing melanoma by age 76. An atypical nevus is not a premelanoma but represents a genetic marker for increased risk of development of melanoma, which may occur anywhere on the skin surface including sun-protected sites. In fact, more than 50% to 75% of melanomas develop on clinically normal skin *de novo*, not in pre-existing melanocytic lesions.

Xeroderma pigmentosa is a rare autosomal recessive disorder associated with a reduced or absent ability to repair DNA damaged by UV light. Consequently, this disorder results in the development of multiple primary cutaneous malignancies, including melanoma as well as BCC and SCC. Individuals are usually diagnosed with their first cancer before the age of 10 years. Unfortunately, the development of skin cancers is relentless.

Congenital melanocytic nevi (CMN) are present at birth or appear within the first 6 months of infancy.⁸ An estimated 1%

to 6% of children are born with CMN. The nevi are classified by size. Small CMN measure less than 1.5 cm in diameter and account for the majority of lesions. Medium CMN measure between 1.5 and 19.9 cm in diameter. Large CMN, also termed *giant congenital nevi*, measure 20 cm or greater. This large size can lead to significant cosmetic and psychosocial implications. The risk of melanoma development in small- and medium-sized CMN is similar to any other area of skin. Melanoma development in small and medium CMN usually occurs after childhood and arises from the dermoepidermal junction, making early detection feasible. Routine prophylactic removal of small and medium CMN is rarely indicated in the absence of signs or symptoms for malignant progression. Conversely, giant congenital nevi carry an increased risk for melanoma, with an estimated rate of 5% to 20%. Of giant congenital nevi that progress to melanoma, 70% are diagnosed prior to age 10 years. Melanoma can originate deep in the epidermis in giant congenital nevi. Consequently, diagnosis within the setting of giant congenital nevi is challenging and may develop deep in the skin with a more advanced primary lesion.

Patients with a giant congenital nevus, especially on the posterior axis, or in conjunction with many satellite lesions are also at risk for neurocutaneous melanocytosis (NCM).^{9,10}

FIGURE 111.1. Examples of skin lesions. A: Giant congenital nevus. B: Lentigo maligna (Hutchinson freckle). C: Melanoma arising in a lentigo maligna (lentigo maligna melanoma). D: Superficial spreading melanoma. (*continued*)

FIGURE 111.1. (Continued) E: Nodular melanoma. F: Acral lentiginous melanoma (ulcerated nodular plantar melanoma with satellite lesions). G: Subungual melanoma. H: Pigmented basal cell carcinoma.

NCM is characterized by the presence of benign or malignant leptomeningeal tumors. Most patients present in the first 2 years of life with neurologic manifestations of increased intracranial pressure, mass lesions, or malignant transformation to melanoma. Magnetic resonance imaging (MRI) findings of NCM may be present, even in asymptomatic children. NCM is associated with an increased risk of development of central nervous system melanoma. Symptomatic NCM is associated with a poor prognosis, even in the absence of malignancy. Chemotherapy is not effective, but shunt placement to reduce intracranial pressure may be palliative.

Clinical Diagnosis and Classification

- 3 Melanoma may have a characteristic appearance (Fig. 111.1). Early detection is key. The ABCD rule, which outlines the warning signs of melanoma, was developed decades ago.¹¹ A stands for *asymmetry*—one half of the lesion does not match the other half when drawing an imaginary line through the center of the lesion. B is *border irregularity*—the edges of the lesion are ragged, notched, or fuzzy. C is *color*—the pigmentation is not uniform throughout the lesion. Varying shades of tan, dark brown to black, or shades of red, white, and/or blue may be present with a mottled appearance. And D is *diameter*—the

width is greater than 6 mm (about the size of a pencil eraser). The seven-point checklist used in Europe incorporates several of the ABCD features with the addition of change. Another useful diagnostic aid is the “ugly duckling” sign. A pigmented lesion that is different from the others should be carefully approached with a high index of suspicion.

The goal of any diagnostic aid is early detection and the ability to differentiate between benign and malignant, with 100% sensitivity combined with high specificity. The ABCD rule, seven-point checklist, and ugly duckling sign all provide relatively high sensitivity but none fulfills all of these criteria, especially with respect to specificity, to distinguish melanoma from benign lesions.

The ABCD criteria may fail to detect an important subset of nodular melanoma (NM), which often does not exhibit the ABCDs and is often less than 6 mm in early development. The ABCD rule is also relatively static without the important critical characteristic of change. Studies have documented early signs of a change in size, shape, or color and the early symptom of persistent itching. One of the best tools for diagnosis of early lesions that may fail to exhibit many of the standard melanoma features is the importance of *change*. Thus, the authors and others have used the D in the ABCD rule to signify “difference.” A difference or change in lesions, especially with respect to size, shape, color, or persistent itching, warrants

evaluation. Furthermore, the nevi on the body should globally share a common look or family resemblance. If one of the nevi seems different from the rest, it should be evaluated with a high index of suspicion. Additionally, if all of the nevi are atypical or irregular but are morphologically similar to one another and are not changing, there may be no reason for individual lesion concern (atypical or dysplastic nevi). However, the presence of atypical nevi represents a risk factor for melanoma development anywhere on the skin surface with development in clinically normal skin, normal nevi, and dysplastic nevi with relatively equal frequency. Thus, excision of all atypical nevi does little for prevention. Education of the patient for early signs and symptoms, particularly change or difference, is key in this clinical scenario.

It must be emphasized that critical diagnostic decisions concerning skin lesions should still always be based on clinical assessments and the history, with attention to melanoma risk factors. The optimum diagnostic aid that combines 100% sensitivity and specificity currently does not exist. The use of all available means including the ABCD and seven-point checklists, ugly duckling sign, difference, photography, dermoscopy, and evolving digital and computer-assisted imaging technologies enhances the ability to diagnose melanoma at the earliest stage.¹¹ The result of using these multiple diagnostic aids is earlier detection of melanoma with higher overall survival rates.

Based on histologic patterns and clinical characteristics, melanomas can be classified into multiple categories, with the four major subtypes being lentigo maligna melanoma (LMM), superficial spreading melanoma (SSM), NM, and acral lentiginous melanoma (ALM).¹² In general, these subtypes derive their prognostic biologic behavior and risk of metastasis based on a secondary correlation with Breslow depth and are thus not independent prognostic factors. Invasive LMM constitutes 10% to 15% of cutaneous melanomas and typically occurs on the chronically sun exposed areas of the head and neck, most often in older individuals. Clinically, the LMM pattern is associated with a significantly higher rate of often extensive and asymmetrical subclinical growth several centimeters beyond the clinical lesion. Failure to completely excise the entire lesion with meticulous margin control results in higher recurrence rates with lethal potential. Additionally, amelanotic and desmoplastic melanoma with neurotropism is more frequent in the lentigo maligna (LM) lesion subtype. LM is not a benign disease as once thought. LM represents in situ melanoma and, with time, progresses to invasive LMM. LMM often begins as a flat brown lesion on chronically sun exposed areas with progression to black and other classic melanoma features over time.

SSM accounts for approximately 70% of cutaneous melanomas. This pattern is the most common in melanomas arising in a pre-existing nevus. SSM is typically characterized by variation in color, irregular borders, and irregular surface and often exhibits the classic melanoma clinical features.

NM occurs in approximately 15% to 30% of patients with cutaneous melanoma and is often the most aggressive of the four types of melanoma because of later detection and rapid growth. In general, NM may be more uniform in coloration than the other types, have regular borders with size less than 6 mm in early lesions, and lack the classic melanoma features initially. Lesion change and difference is important for early detection.

ALM is a distinct clinicopathologic variant of melanoma that most commonly occurs on the hands, feet, fingers, and toes as well as in subungual locations (Fig. 111.1). ALM represents only 2% to 8% of melanoma in whites but 35% to 60% in people of color. Later detection frequently occurs because of location that is not easily or routinely examined and a low index of suspicion. When corrected for Breslow depth, the overall prognosis for ALM appears similar to the other subtype categories. In subungual locations, this phase can appear as an irregular, tan-brown streak in the nail that originates from the base of the nail bed. More than three

fourths of subungual melanomas involve the great toe or thumb, and they can be confused with subungual hematoma.

Other rare melanoma subtypes deserve brief mention. Mucosal, anal, and vulvovaginal melanomas are associated with a poorer prognosis, possibly related to advanced disease at presentation with late detection and high vascularity at the lesion site. Desmoplastic melanoma is associated with a higher rate of neurotropism and lower rate of lymph node metastases.^{13–15} Small cell or nevoid melanoma often lacks any of the classic features, is difficult to accurately diagnose without expert dermatopathology interpretation, and thus may be initially more frequently misdiagnosed. And amelanotic melanoma, occurring in 3% to 4% of cases, is often associated with late detection due to lack of pigment and failure to diagnose early.

Staging and Prognostic Factors

- 4 A great deal of information is available regarding various factors that correlate with the clinical outcome of patients with melanoma. Some of these prognostic factors, such as microstaging and nodal status, are of sufficient independent significance to be incorporated into staging systems with known survival rates. Other prognostic factors, such as tumor ulceration and microscopic versus macroscopic nodal disease, have also been found to be significant variables that influence survival and have been incorporated into the staging system.

Microstaging

One of the most important prognostic features of cutaneous melanoma is the stage of development of the primary tumor. The microstaging method that is used routinely was originally described by Breslow.¹⁶ This method classifies the primary tumor according to its thickness in millimeters, as measured with an ocular micrometer, from the top of the granular layer to the base of the tumor. Many investigators have documented an inverse correlation between tumor thickness and survival. The largest series of 17,600 patients reported by Balch et al.¹⁷ is summarized in Table 111.1. The ulceration status and mitotic rate are also independent factors that are used to determine microstaging of the primary lesion.^{17,18} Prior to the use of the Breslow microstaging method, melanomas were staged according to the level of invasion into the histologic layer of skin. This was known as the Clark level of invasion and comprised five levels (I, in situ lesions; V, subcutaneous involvement). Several studies have confirmed that Breslow thickness conveys more accurate prognostic information than does the determination of Clark level.^{17,19}

The presence of regional lymph node metastases is associated with a worsening prognosis. The tumor burden (microscopic vs. macroscopic disease) of involved lymph nodes has an inverse correlation with long-term survival.^{17,19} The 5-year survival rate for patients with involved lymph nodes ranges from 70% to 25%, based primarily on tumor burden and ulceration status of the primary lesion (Table 111.2). The use of sentinel lymph node biopsy (SNLB) has identified a subgroup of patients with micrometastatic nodal disease who have a favorable prognosis compared with patients with macroscopic nodal involvement. This information has been incorporated in the staging system as well.

Clinical and Pathologic Staging

The American Joint Committee on Cancer (AJCC) developed a five-stage system that divides melanomas according to tumor thickness (T), nodal status (N), and metastatic disease (M).^{17,19} The current system was updated in 2009 and is summarized in Table 111.3. There are five stages based on prognosis: stage 0

Modified from Balch M, Soong SJ, Gershenwald JE, et al. Prognostic factors analysis of 17,600 melanoma patients: validation of the American Joint Committee on Cancer Melanoma Staging System. *J Clin Oncol* 2001;19:3622–3634.

(in situ melanoma), stage I (local disease), stage II (local disease), stage III (regional nodal, in-transit, or satellite metastases), and stage IV (distant metastases; Table 111.4). In general, increasing stage is associated with decreasing survival (Table 111.1).

Other Prognostic Factors

The major prognostic factors that predict survival in melanoma patients have been accounted for in the AJCC staging system—namely, tumor microstaging, ulceration, nodal status, and distant metastases.^{17,19} The presence of ulceration in a melanoma appears to be associated with a poorer prognosis. Men have a higher proportion of ulcerated lesions than women (27% vs. 19%, respectively). Although ulceration appears to correlate with thickness of the melanoma, the presence of ulceration is an independent prognostic factor and has been included in the staging system.^{17,19} Additionally, a higher mitotic rate of 1.0 mm² or greater is an independent prognostic factor of both nodal involvement and survival.^{18,20,21} The presence of angiolymphatic invasion is also a poor prognostic sign.

Treatment of Primary Melanoma

Biopsy. For localized melanoma, the tumor thickness (Breslow depth of invasion) is the single variable that most accurately determines therapy and prognosis. The ulceration status and mitotic rate also represent independent prognostic variables. A full-thickness biopsy with 1- to 2-mm margins only, to the adipose tissue, is preferred for any lesion highly suspect for melanoma.²² If the melanoma is transected with a partial-thickness shave biopsy, the ability to obtain an accurate measurement of tumor thickness is lost. Therefore, a superficial shave biopsy is never recommended for a suspect pigmented lesion. Saucerization, which uses a curved blade to perform a deeper shave biopsy down to the subcutaneous fat, is acceptable.

Excisional biopsy with 1- to 2-mm margins is the preferred method for suspect lesions to provide the pathologist a total specimen for histologic interpretation and accurate microstaging. Performing a wide excision as the first step, especially on the trunk or head and neck, is not recommended, as several benign and malignant lesions can mimic melanoma and because doing so may result in the inability to accurately perform SLNB. Formalin-fixed, paraffin-embedded, permanent sections should be used for biopsy diagnosis of primary cutaneous melanoma to accurately determine tumor thickness and other histopathologic prognostic variables. Frozen sections have no role in the diagnosis or microstaging of primary melanoma. If the lesion is a melanoma, the excisional biopsy represents the first stage of a two-stage procedure. The second stage is re-excision with margins generally ranging from 0.5 to 2.0 cm, with or without SLNB, depending primarily on the tumor thickness. When biopsying a suspected melanoma on the extremities, it is critical that the biopsy be oriented on the long axis of the extremity, parallel to the lymphatics. Performing a biopsy oriented transversely on the extremity may not only compromise the accuracy of lymphatic mapping but also may obligate the patient to a skin graft to close the subsequent wide excision defect.

For suspicious lesions that are too large for complete excision and those that are located where the amount of skin is critical in terms of functional or cosmetic results, an incisional biopsy may be performed with an elliptical incision, deep saucerization shave to adipose or deep dermis in thick skin areas, or a punch biopsy. Incisional biopsies for melanoma do not increase the risk of local recurrence and distant metastasis or affect patient survival. They should generally be performed on the most raised or most pigmented area of the lesion to maximize the obtainable diagnostic and prognostic information. The most raised area usually corresponds to the maximal thickness of the lesion, but not always. Several incisional biopsies can be obtained from different areas for large lesions with multiple morphologic features. In the scenario of incisional biopsy with significant remaining lesion, complete excision for accurate microstaging should be considered prior to definitive treatment, unless the lesion is already 1 mm or greater in Breslow depth.

STAGING

AMERICAN JOINT COMMISSION ON CANCER MELANOMA STAGING SYSTEM,
TNM DEFINITIONS

PRIMARY TUMOR

TX: Cannot be assessed (shave biopsy, regressed lesion)

T0: Unknown primary

Tis: In situ melanoma

T1: ≤ 1 -mm Breslow thicknessa. Without ulceration and mitosis $< 1 \text{ mm}^2$ b. With ulceration or mitosis $\geq 1 \text{ mm}^2$

T2: 1.01 to 2.00 mm

a. Without ulceration

b. With ulceration

T3: 2.01 to 4.00 mm

a. Without ulceration

b. With ulceration

T4: > 4 mm

a. Without ulceration

b. With ulceration

REGIONAL LYMPH NODE INVOLVEMENT

NX: Cannot be assessed (previously removed)

N0: No regional node metastasis

N1: Metastasis in one regional node

a. Micrometastasis (diagnosed by SLNB or elective lymph node dissection)

b. Macrometastasis (clinically palpable or found on imaging studies, confirmed histologically, or gross extracapsular extension)

N2: Metastasis in two to three regional nodes

a. Micrometastasis

b. Macrometastasis

c. In-transit or satellite metastasis without nodal metastasis

N3: Metastasis in ≥ 4 regional nodes, matted nodes, or in-transit or satellite metastasis with positive metastatic nodes

DISTANT METASTASIS

MX: Cannot be assessed

M0: No distant metastasis

M1a: Distant skin, subcutaneous, or lymph node metastasis with normal LDH

M1b: Lung metastasis with normal LDH

M1c: All other visceral metastases with a normal LDH or any distant metastases with an elevated LDH

SLNB, sentinel lymph node biopsy; LDH, lactate dehydrogenase.

Metastatic Workup

In an attempt to standardize staging workup for melanoma, the National Comprehensive Cancer Network (NCCN) has published guidelines.²³ There are three basic reasons to perform a metastatic workup following the diagnosis of primary cutaneous melanoma: (a) for staging and prognosis, (b) to detect an early metastasis with potential survival benefit, and (c) to avoid morbidity of an extensive surgical procedure by detection of a distant metastasis.²⁴ The best test for the staging workup still starts with a history (a focused review concentrating on constitutional, respiratory, neurologic, hepatic, musculoskeletal, gastrointestinal, skin, and lymphatic systems) and physical examination (total body skin examination, palpation of lymph nodes). Routine imaging (chest x-ray, computed tomography [CT] scans, positron emission tomography

[PET] scans) and blood studies (complete blood count, comprehensive metabolic profile, liver function tests, serum lactate dehydrogenase levels) in asymptomatic, clinically node-negative patients are low in both sensitivity and specificity and are not necessary.^{25–28} False-positive staging tests are common and lead to more tests and patient distress. SLNB represents the best baseline staging test, with both relatively high sensitivity and specificity in patients at significant risk for metastasis. The ability to detect stage IV disease with routine studies is small if the SLNB is negative. Both ultrasound and PET scanning have been examined as methods of identifying nodal metastases prior to surgery. While they detect disease in a minority of patients, the size of most metastases to the regional nodes are below the threshold of ultrasound or PET to detect, so this is not a cost-effective strategy.^{29–31} If a thorough history and physical and detailed review of systems reveals no signs or

^aClinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastasis. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

^bPathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes.

^cThere are no stage III subgroups for clinical staging.

From Balch M, Buzaid AC, Soong SJ, et al. Final version of the American Joint Committee on Cancer Staging System for Cutaneous Melanoma. *J Clin Oncol*. 2001;19:3635–3648. Reprinted with permission from the American Society of Clinical Oncology.

symptoms suspicious for regional or distant disease, then no further staging is necessary. However, a high index of suspicion should be maintained and a thorough symptom-directed workup should be initiated for any worrisome finding on the history and physical.

Approximately 5% to 10% of newly diagnosed melanoma patients present with clinically involved lymph nodes. Any clinically suspicious node should be confirmed by fine needle aspiration (FNA) biopsy, as enlarged lymph nodes may be reactive (particularly after a biopsy). Ultrasound-guided FNA biopsy can be useful in cases where the suspicious node is difficult to biopsy by hand. Patients documented to have macroscopic regional disease should undergo complete staging prior to definitive surgery, as a significant percentage may have more advanced regional or distant disease that may alter surgical therapy.^{32,33} Staging should include a serum lactate dehydrogenase (LDH) level; MRI of the head and either CT of the chest, abdomen, and pelvis; PET scan; or combined CT/PET scan. For patients with involved groin nodes, CT scan is recommended to

visualize the pelvic nodes, as this may help to determine the extent of inguinal node dissection. Workup for stage IV disseminated melanoma is often dictated by clinical trial protocols. Follow-up test guidelines are similar to these workup principles (Table 111.5).

Surgical Excision of Primary Melanoma

- The primary purpose of a melanoma excision is to prevent local recurrence due to persistent disease. For melanoma in situ, excision margins of 0.5 cm are indicated. For invasive melanoma, wide excision of the primary tumor, with margins generally ranging from 1 to 2 cm, is indicated for local control. The optimal margin width remains somewhat controversial. The historical approach of excising all primary melanomas with a 3- to 5-cm margin is extinct. At least five randomized controlled trials failed to demonstrate a difference in overall survival or local recurrence with narrow (1- to 2-cm) versus wide (3- to 5-cm)

TABLE 111.5

TREATMENT

FOLLOW-UP GUIDELINES: INTERVAL FREQUENCY AND TESTS

Shorter intervals may be considered for patients with dysplastic nevus syndrome or those who have difficulty with self-examinations. Coordination is necessary dermatologist and primary care provider/internist/or medical oncology team.

margins³⁴ (Table 111.6). Of note, one trial³⁵ demonstrated an increased risk of locoregional recurrence with 1-cm versus 3-cm margins for melanoma more than 2 mm thick. Based on these trials, current consensus guidelines recommend margins of 1 cm for melanomas 1 mm or less thick, 2 cm for melanomas greater than 2 mm thick, and 1 to 2 cm for melanomas 1 to 2 mm thick. For this last group, the size of the margins should be based on the anatomic location of the melanoma and the morbidity of excising 2 cm versus 1 cm, including the need for an advancement flap or skin graft (Table 111.7). For several locations, such as melanomas on the head and neck, the maximum margins attainable are dictated by anatomic limitations. Subungual melanomas require amputation of the digit. Perianal melanoma can often be treated by wide excision, but melanoma of the anal mucosa may require abdominoperineal resection (APR). A complete staging workup should be performed before proceeding with APR, as these patients have a very high rate of regional and distant disease.³⁶

For the clinically ill-defined LMM, histologic confirmation of negative margins is important, and it should be emphasized that these margin recommendations may not apply to in situ LM and invasive LMM on the head and neck.^{37,38} LM and LMM are often associated with extensive subclinical involvement to as much as several centimeters beyond the clinical component. Careful and complete margin control, including excision of the lesional trailing edge of atypical melanocytic hyperplasia, often beyond the standard margins, may be necessary for complete surgical resection of LM/LMM on the head and neck.

Treatment of Regional Metastatic Melanoma

Lymphadenectomy Results and Indications. Surgical excision of metastases to regional lymph nodes is potentially curative therapy. The 5-year survival rate for patients who undergo lymphadenectomy for clinically positive involved

Margins may need to be modified based on anatomic considerations but still require histologic confirmation of tumorfree margins. For clinically ill-defined lentigo maligna/lentigo maligna melanoma, wider margins may be required for histologic confirmation of tumorfree margins.

nodes (AJCC stage III) ranges from 25% to 70%. In addition, for those patients not cured by lymphadenectomy, resection can avoid potential pain associated with tumor enlargement, skin breakdown, and tumor necrosis (Fig. 111.2). Only 5% to 10% of patients who first present with the diagnosis of melanoma have clinical evidence of nodal metastases, approximately 85% to 90% have localized disease, and the remaining 5% have distant metastases. In less than 3% of patients, a diagnosis of melanoma is made in the absence of a definable primary lesion.³⁹ When patients present with isolated nodal disease from an unknown primary site, the results of lymphadenectomy are similar to those for patients with known primary tumors. For patients with melanoma 1 mm thick or greater who present with clinically negative nodes, SLNB should be considered to determine whether therapeutic lymphadenectomy is indicated.⁴⁰

FIGURE 111.2. Patient with large melanoma axillary involvement with skin ulceration.

Sentinel Lymph Node Biopsy

Morton et al.⁴¹ were the first to develop the concept of “sentinel lymph nodes” in the nodal basins draining cutaneous melanomas. They hypothesized that melanoma involvement of a nodal basin develops in an orderly fashion with metastasis to the sentinel lymph node as the first step in that process. With the intradermal injection of a blue dye, these investigators were able to identify sentinel lymph nodes 90% of the time. If the sentinel node was negative for melanoma, the remaining lymph nodes were also free of involvement in at least 96% of cases. These results have been confirmed by multiple other groups.^{42–44}

Two tracers are typically used for identifying the sentinel lymph nodes: a blue dye—1% isosulfan blue (Lymphazurin)—and a radiolabeled colloid solution. Lymphazurin carries a risk of allergic reaction in 0.5% to 2.0% of patients, which can be life threatening.⁴⁵ Methylene blue dye can also be used, without risk of allergic reaction, although this should be diluted as it can cause skin necrosis if not completely resected. One to 4 hours before surgery, a radiolabeled colloid solution is injected intradermally. The injection site is around the primary tumor site or excision site, taking care to avoid injecting directly into any residual tumor. Lymphoscintigraphy imaging is then performed, which is critical in that it can identify sentinel nodes outside the traditional nodal basin. The blue dye is injected intradermally in the operating room a few minutes before the procedure. Using a handheld gamma detector probe, the surgeon is able to identify the sentinel lymph node location through the skin, thereby limiting the incision necessary to find the node. Blue-stained lymphatics and lymph nodes can be directly visualized (Fig. 111.3). The combined use of the blue dye plus the radiolabeled colloid enables the detection of the sentinel node in more than 95% of cases.⁴⁴ The technique of SLNB is most often performed in conjunction with the wide excision of the primary tumor. It can routinely be performed as an outpatient procedure.

Once the sentinel lymph node is removed, it is processed by the pathologist by step sectioning the entire node into multiple sections for routine hematoxylin and eosin staining. This is done to examine for micrometastases that could be missed by the standard approach to examining nodes, which involves bivalving the lymph node and performing an examination of only one section. If serial sectioning and staining are negative for metastasis, then immunohistochemical staining for melanoma markers such as S-100, Melan-A, and HMB-45 is performed.⁴⁶ These stains can identify microscopic clusters of tumor cells that are hard or impossible to identify by hematoxylin and eosin staining. The thoroughness of assessing the

FIGURE 111.3. Blue dye tracking up a lymphatic vessel to a blue-stained lymph node.

FIGURE 111.4. Technique of groin dissection.

sentinel lymph nodes for metastatic disease has resulted in much more accurate staging of patients. Micrometastases to lymph nodes has been incorporated in the current staging system as described above.

If the sentinel lymph node is positive for melanoma, then complete lymph node dissection (CLND) (Fig. 111.4) is indicated based on potential survival and clinical benefit. The interim results of the Multicenter Selective Lymphadenectomy Trial I (MSLT-I), which randomized patients to wide local excision (WLE) alone or WLE in combination with SLNB and CLND for a positive lymph node demonstrated that the survival of patients with regional metastases detected by SLNB who underwent CLND was significantly improved over those patients who underwent CLND for a regional recurrence (66.2% vs. 54.2%, $p < 0.02$).⁴⁷ An unresolved question is whether every patient with a positive sentinel lymph node requires CLND. Several attempts to retrospectively identify clinical or histologic factors that may predict the absence or presence of disease within the non-sentinel nodes have not identified any absolute way to determine who requires additional surgery, although a combination of the Breslow depth and amount of disease within the sentinel lymph node seems promising. The results of the ongoing MSLT-II trial, which randomizes patients with a positive sentinel lymph node to CLND or serial ultrasonography of the regional basin, will provide more information regarding the benefit of CLND for sentinel lymph node-positive patients. Until that time, CLND for a positive sentinel lymph node remains the standard of care in the treatment of melanoma.

Patients with primary melanomas equal to or greater than 1 mm thickness and clinically negative nodes should be con-

sidered for SLNB. For some subgroups of patients with melanoma Breslow depth of 0.75 to 1.0 mm, SLNB may be considered. These subgroups include younger patients, evidence of ulceration or angiolymphatic invasion, extensive dermal regression to 1 mm, or 1 mitosis/mm² or greater in the primary tumor.^{20,48–50} Reasons not to perform SLNB include significant medical comorbidities or the patient does not desire SLNB after an informed discussion.

Adjuvant Therapy

Although the prognosis for patients with early-stage cutaneous melanoma is quite good, less than 50% of patients with thick primaries (i.e., >4 mm) or regional node involvement are cured by surgery alone. The development of effective adjuvant therapy capable of increasing postsurgical survival in high-risk groups of patients has been a long-standing goal of clinicians. Unfortunately, numerous randomized trials evaluating systemic chemotherapeutic agents (most notably dacarbazine), nonspecific immunotherapy (such as bacille Calmette-Guérin), and tumor-specific vaccines in the adjuvant setting have failed to demonstrate any impact on survival.^{51–53}

Interferon- α 2b (IFN- α) has a variety of modulatory effects on the immune system that could enhance antitumor reactivity. IFN- α has been reported to have antitumor activity in patients with metastatic disease. In 1996, Kirkwood et al.⁵⁴ reported the effectiveness of IFN- α to improve disease-free and overall survival rates of patients with stage IIb (>4 mm) or III disease after surgery. In this multi-institutional prospective randomized trial, 287 high-risk patients with deep primary (>4 -mm) tumors or positive nodes were randomly assigned after surgery to either postoperative adjuvant treatment with IFN- α 2b or to observation. IFN- α 2b therapy significantly increased median overall survival by 1 year and produced a 24% improvement in the 5-year overall survival rate (46% for IFN- α 2b patients vs. 37% for observation patients). Based on these results, the Food and Drug Administration (FDA) approved the use of adjuvant IFN- α 2b after surgical resection of stage IIb or III melanoma. Follow-up studies have raised concerns about the relative efficacy of IFN- α in this setting; however, in healthy melanoma patients at high risk of relapse, this is the only known adjuvant therapy that should be considered.⁵⁵

Treatment of In-Transit Disease

In-transit disease and satellitosis develop in 5% to 8% of patients with melanomas thicker than 1.5 mm.⁵⁶ These are classified as stage III disease but portend not only a poor prognosis but can be a challenge to treat. Treatment involves either local excision or ablation, or regional chemotherapy. Surgical excision is the optimal management when the number of lesions is small and complete excision is possible. Prior to proceeding with surgery, a complete staging workup for metastatic disease is recommended, as these patients often harbor distant disease. When surgery is not feasible, a number of intralesional therapies (such as granulocyte-macrophage colony-stimulating factor) or ablative therapies (radiation, cryotherapy, electrodesiccation, laser ablation, photodynamic therapy) have been employed with limited success. When the in-transit disease is unresectable but limited to an extremity, regional administration of high-dose chemotherapy can be effective in controlling disease.

Isolated limb perfusion (ILP) uses an extracorporeal membrane oxygenator (as is used with cardiac surgery) to deliver chemotherapy doses 15 to 25 times higher than can be obtained with systemic delivery. The surgeon isolates the vessels and uses a tourniquet to prevent systemic uptake of the agent(s). Using the bypass machine, the limb is perfused with hyperthermic (38°C to 40°C) chemotherapy solutions, most

commonly melphalan. After 60 to 90 minutes of treatment, the drug is flushed from the circulation and systemic circulation is restored. Response rates between 80% and 90% are reported, with complete response rates between 40% and 65%.^{56–58} In some cases, these can be quite durable. Toxicities can range from mild erythema and edema to epidermolysis, functional impairment, and in extremely rare cases a need for amputation.

Because of the complexities involved in scheduling and performing ILP, it is currently available at only a few select centers. A less invasive and less toxic approach is the use of isolated limb infusion. Rather than surgical isolation of the vessels, percutaneous catheters are placed radiologically in the artery and vein and connected to an extracorporeal circuit incorporating a heating coil. A tourniquet is placed on the extremity, but because some systemic uptake is anticipated, lower doses of chemotherapeutic agents are used. Some studies have reported response rates equal to ILP, although others report slightly lower response rates.^{59,60}

Treatment of Disseminated Melanoma

Evaluation for Metastatic Disease and Clinical Course. The follow-up evaluation for patients with AJCC stage I, II, or III melanoma who are rendered tumorfree by surgery should include regular histories and physical examinations. The use of extensive and frequent radiographic studies and blood work in asymptomatic, clinically diseasefree patients is rarely productive.^{23,24} For AJCC stage IA (≤ 1 mm), the NCCN recommends that patients should undergo a history and physical examination with emphasis on skin and nodal examinations every 3 to 12 months as clinically indicated. For AJCC stage IB to III, patients should undergo a history and physical examination every 3 to 6 months for 3 years, then every 4 to 12 months for 2 years, then annually as clinically indicated (Table 111.5). The use of chest radiographs and blood work, as well as other imaging scans, when clinically indicated, is based on the history and physical examination.

Melanoma can disseminate to any organ. The most common sites of recurrence are skin, subcutaneous tissues, and distant lymph nodes, followed by visceral sites. Common visceral sites of metastasis, in order of decreasing occurrence, are the lung, liver, brain, bone, and gastrointestinal tract. Most patients who die with disseminated disease have multiple organ involvement. Frequently, the cause of death is respiratory failure or brain complications. Patients with disseminated disease have a poor prognosis, with a mean survival of approximately 6 months. Cure with any treatment is rare. Selection of treatment or a decision against treatment should be based on several factors, including the patient's medical condition, the potential for palliation, and the impact of treatment on quality of life.

Surgery

While surgery is rarely considered for patients with metastases, melanoma remains an exception, with documented long-term survival among patients who undergo resection of metastatic lesions. Surgery should be strongly considered for palliative purposes, but also should be considered in select patients with stage IV melanoma with a goal of prolonged diseasefree survival. Careful selection is key, and most patients who present with metastases are not candidates for resection. The decision to pursue surgery should be made on the age and health of the patient, the number and locations of the metastases and ability to achieve negative margins, the morbidity of the operation, and the diseasefree interval. Patients with single versus multiple lesions and longer diseasefree intervals, as well as those in good overall health, are the ideal candidates. Before

surgery, a careful search for additional sites of disease should include a thorough history and physical, serum LDH, CT/PET scan, and MRI of the brain. With careful selection, excellent 5-year survivals have been reported in patients undergoing complete resection of skin, soft tissue, and lung, and even liver, gastrointestinal, and brain metastases.^{61–68}

Radiation Therapy

Although generally thought to be a radioresistant tumor, melanoma can respond to radiation therapy.^{69,70} Radiation therapy is commonly used for palliation of bone pain secondary to metastatic disease or brain metastasis. The average survival after brain irradiation for melanoma is approximately 4 months.

Radiation therapy has also been utilized as an adjuvant to the resection of high-risk nodal metastases, typically defined as having extracapsular extension, four or more positive nodes, or recurrent nodal disease. Several studies have reported improved regional control rates when radiation was combined with surgery, especially for cervical metastases, although these are primarily retrospective.^{71–74} A prospective trial of adjuvant nodal irradiation for node-positive melanoma patients showed an in-field recurrence rate of 7%.⁷⁵ However, morbidity is significantly increased when radiation is added to a CLND, and there is no prospective data to suggest an improvement in overall survival. A large, nonrandomized retrospective review of patients with high-risk cervical metastases from the Sydney Melanoma Unit compared patients who received adjuvant radiation to those who did not and found only a nonsignificant 10% reduction in recurrence and no overall survival benefit.⁷⁶ A prospective randomized trial by the Tasman Radiation Oncology Group is presently accruing patients.

Chemotherapy

Melanoma is responsive to few chemotherapeutic drugs.^{49–53} The best single agents for treatment of melanoma are dacarbazine (DTIC), the nitrosoureas, vinca alkaloids, and cisplatin, which have objective response rates in the range of 10% to 20%. Conventionally, objective responses have included complete disappearance of all known tumor sites (complete response) and reduction of more than half in all assessable tumor (partial response). Complete responses are rare and nearly always of brief duration (< 6 months). Responses are more frequently observed in patients with tumor in the skin, subcutaneous tissue, lymph nodes, or lung. Combination chemotherapy with the potential of drug synergy has been used with limited success in the treatment of metastatic melanoma. No evidence indicates that combination chemotherapy offers better results than single-agent DTIC at this time.

Immunotherapy

The rapid evolution of recombinant DNA technology has resulted in the availability of cytokines, such as the interferons and interleukins, that can be administered to modulate a patient's immune response.^{36–40} These biologic agents have been used in immunotherapeutic trials for metastatic melanoma and demonstrate that an antitumor immune response can be generated in select patients. A significant advance in melanoma immunotherapy has been associated with the use of interleukin-2 (IL-2). IL-2 is a cytokine secreted by antigen-activated helper T cells and was initially discovered because it was a T-cell growth factor. Subsequently, it was found to have many other immunologic effects, and it appears to have an important role in the enhancement of immune responses. Mulé et al.⁷⁷ discovered that the in vivo administration of IL-2 in preclinical animal

FIGURE 111.5. A: Patient with disseminated melanoma metastatic to multiple cutaneous sites. B: After several courses of therapy with lymphokine-activated killer cells and interleukin-2, the patient had a complete response. (Courtesy of Steven A. Rosenberg, M.D., Surgery Branch, National Cancer Institute, Bethesda, MD.)

models resulted in dramatic tumor regression. In clinical studies, the administration of IL-2 resulted in a 15% to 20% response rate in patients with advanced melanoma.⁷⁸ Approximately 5% of patients have a complete response that has been durable for prolonged periods (Fig. 111.5). This latter result prompted the FDA to approve IL-2 for the treatment of metastatic melanoma.

There has been significant interest in the use of vaccines as a treatment for malignant melanoma, fueled by the lack of efficacy of standard chemotherapy, evidence of the immune system's ability to recognize and eradicate melanoma, and the discovery of unique melanoma tumor-associated antigens. Unfortunately, results of using peptides, gangliosides, or allogeneic cells have been disappointing.^{79,80} A more promising approach may be the use of dendritic cells (DCs). DCs are potent antigen-presenting cells of the immune system that are capable of sensitizing naive T cells to respond against tumor antigen. DCs can be "pulsed" with tumor antigen in the form of peptides, whole tumor cells, lysates of tumor cells, or genes encoding antigen. Animal studies have shown that antigen-pulsed DCs can cause the regression of established tumors by intradermal or intravenous administration. The administration of IL-2 with DC therapy has improved the antitumor response rate in animal studies.⁸¹ In humans, antigen-pulsed DCs have resulted in complete responses in patients with stage IV melanoma.⁸² Numerous studies are being conducted to evaluate DC vaccine therapy in the treatment of melanoma.

A promising area of research in melanoma is direct immune modulation through the blockade of cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), a cell surface molecule on T cells that is upregulated in activated cells and serves as an immunologic "brake." Humanized monoclonal antibodies (mAb) that block CTLA-4, thus releasing the brake on T cells, have been shown to augment the antitumor response.⁸³ Two such antibodies, MDX-010 and ticilimumab, have been tested

in stage IV melanoma with promising results.^{84,85} Several studies of anti-CTLA-4 mAb alone or in combination with other immunotherapies, in both the adjuvant and metastatic settings, are ongoing.

As opposed to active immunotherapy, where an agent is delivered with the goal of stimulating or augmenting the host's immune response (such as a vaccine), passive immunotherapy involves delivering components of the immune system that have already been sensitized to tumor antigens. One example of this in the treatment of metastatic melanoma is the use of antitumor reactive T cells, known as *adoptive immunotherapy*. One source of these T cells is from the tumor itself, known as tumor-infiltrating lymphocytes (TIL). In clinical studies, Rosenberg et al.^{86,87} have reported that patients with advanced melanoma treated with the combination of TIL, IL-2, and chemotherapy can result in response rates between 35% and 50%. Lymphodepletion of patients before adoptive immunotherapy may improve these results. One drawback to the use of TIL for adoptive immunotherapy is the need to harvest adequate tumor from patients with stage IV disease, which may be difficult. Alternative approaches include delivering a vaccine to the patient and then using T cells from the vaccine-draining lymph nodes,⁸⁸⁻⁹⁰ or retroviral gene transduction of peripheral blood mononuclear with the genes for the TCR- α and β chains against a melanoma-associated antigen.⁹¹

Biochemotherapy

Combinations of IL-2 and/or IFN- α with chemotherapy, known as biochemotherapy, have shown significant improved response rates compared with chemotherapy alone or cytokines alone. As might be expected, these regimens are more toxic than the component therapies by themselves. One of the biochemotherapy regimens that has demonstrated a significant

response rate (i.e., 64%, including 21% complete and 43% partial) with moderate toxicity is a combination of cisplatin, vinblastine, dacarbazine, IL-2, and IFN- α .⁹²⁻⁹⁵ Unfortunately, a randomized trial comparing this regimen to cisplatin, vinblastine, and dacarbazine alone demonstrated that while the addition of the cytokines produced slightly higher response rates and improved median progression-free survival than chemotherapy alone, this was not associated with improved overall survival or durable responses.⁹⁶ In addition, a meta-analysis of trials of biochemotherapy versus chemotherapy in patients with metastatic melanoma also showed that although biochemotherapy improves response rates, this does not appear to translate into a survival benefit.⁹⁷ Clinical trials of other regimens are still ongoing, and biochemotherapy may be considered in select patients with advanced melanoma who are thought to be able to tolerate the toxicities of the therapy.

NONMELANOMA SKIN TUMORS

- 7** BCC and SCC account for 96% of new NMSCs. These tumors are derived from epithelial origin.¹⁻³ The ratio of BCC to SCC is approximately 4:1. The annual incidence of BCC and SCC in the United States alone exceeds 1 million cases. The public health burden on the U.S. population from NMSC, for which the incidence is rapidly rising, is highly significant. Patients with NMSC have an excellent prognosis, with 90% to 99% curable with appropriate treatment and less than 1% resulting in death. SCCs account for 75% of NMSC deaths, which are estimated at 2,000 to 2,500 per year.

Etiology

Both BCC and SCC are most commonly induced by significant exposure to UV light from the sun or tanning booths.² These cancers are the predominant neoplasms of the head, neck, trunk, lower legs, and extensor arms and hands where sun exposure is common. Skin cancer is a significant occupational hazard for people who work outdoors. The phenotype at increased risk is one with fair skin who sunburns and freckles easily, has blue eyes, and has red or blonde hair. Melanin pigment in the skin appears to be the protective factor.

A number of genetic syndromes are associated with an increased risk of developing NMSC, including Gorlin syndrome, xeroderma pigmentosa, and albinism. Gorlin syndrome is an autosomal dominant disorder associated with multiple BCCs, palmoplantar pits, jaw cysts, frontal bossing, and hyper-telorism. Albinism is a disorder characterized by a partial or complete deficiency in melanin production and, thus, loss of protective pigment. Another factor associated with NMSC, primarily SCC, is chronic exposure to chemicals such as arsenic and hydrocarbons (found in coal tars, soot, and asphalt). Cigarette smoking has been associated with SCC of the lip and mouth. Human papillomavirus has been associated with cutaneous SCC in the genital and acral/periungual areas. Radiation has been associated with both SCC and BCC.

Basal Cell Carcinoma

BCC is the most common form of skin cancer. These epithelial-derived tumors can be divided into various subtypes according to clinical appearance, histologic pattern, and biologic behavior. Although BCCs rarely metastasize, they are characterized by slow but relentless and destructive local invasion that results in high morbidity without treatment. The subclinical local invasion may be deep, extensive, and asymmetric, with finger-like extensions several centimeters beyond the clinical borders.

The most common subtype of BCC is the well-circumscribed nodular variety. These tumors often present as

FIGURE 111.6. Basal cell carcinoma near the eye.

pearly papules or nodules with telangiectases. They may be pruritic and bleed occasionally. With time, the center ulcerates to create peripheral “rolled” borders; such ulcerating BCCs are called *rodent ulcers* (Fig. 111.6). Occasionally, the lesions are deeply pigmented and nodular and can be confused with melanoma. This variant has been called *pigmented BCC* (Fig. 111.1H). The histologic features of these tumors demonstrate isolated areas of basaloid tumor islands arising from the epidermis with peripheral palisading of nuclei and stromal retraction. In some cases, the BCC has histologic features of squamous metaplasia with keratinization. These tumors have basosquamous differentiation and can become more aggressive and develop regional lymphatic spread.

The most locally aggressive type of BCC is characterized by a diagnostic histopathologic aggressive growth pattern, known as morpheaform, sclerosing, or fibrosing BCC (Fig. 111.7). Clinically, these tumors may be more subclinical, are flat, and appear to be scarlike. They have a significant incidence of

FIGURE 111.7. Morpheaform basal cell carcinoma of the scalp.

TABLE 111.8**BASAL CELL CARCINOMA: HIGHER RISK FACTORS FOR SUBCLINICAL INVASION AND RECURRENCE**

- Recurrent tumor
- Anatomic location
 - High risk:* Central face, eyelid, eyebrow, periorbital, nose, lip, chin, mandible, temple, ear, in front or behind the ear, genitalia, hand and foot
 - Medium risk:* Cheeks, forehead, scalp, and neck
 - Low risk:* Trunk, extremity (excluding hand/foot)
- Size
 - Lesions ≥ 6 mm on high-risk area
 - Lesions ≥ 10 mm on medium-risk area
 - Lesions ≥ 20 mm on low-risk area
- Histologic subtype pattern
 - Aggressive growth (morpheaform, fibrosing, sclerosing, infiltrating)
 - Micronodular
- Ill-defined clinical borders
- Perineural invasion
- Development in sites of prior radiation
- Immunosuppression

recurrence because of the isolated, fingerlike fronds of basal cell tumor cells that may deeply invade the surrounding structures well beyond the clinical margins of the lesion. These small, fingerlike islands are often missed with standard histologic margin control.

Clinically, superficial BCCs are scaly pink to red lesions. Frequently, they are confused with psoriasis or other eczematous, scaly dermatoses. Although these tumors are usually relatively superficial, extensive superficial subclinical involvement is common. Numerous risk factors are associated with possible extensive subclinical invasion and increased rates of local recurrence for BCC after standard treatment, including surgical excision (Table 111.8).

Squamous Cell Carcinoma

SCC is the second most common form of skin cancer and is derived from the epithelial keratinocyte. SCC can deeply invade surrounding structures and metastasizes most commonly to regional lymph nodes. In immunosuppressed transplant individuals, SCC is the most common skin cancer, occurring 65 to 250 times more frequently than in the general population. SCC in these individuals tends to have more aggressive behavior.

Several precursor lesions to invasive SCC exist, most commonly actinic keratoses and Bowen disease (in situ SCC). Erythroplasia of Queyrat, another precursor lesion, represents SCC in situ on the glans penis. Histologically, SCC shows malignant degeneration of epithelial cells with differentiation toward keratin formation. SCC often appears clinically as a nonhealing sore with ulceration and inflammatory pink borders or an erythematous papulonodule with overlying keratotic crust or ulceration (Figs. 111.8 and 111.9). These tumors most often arise in chronically actinically damaged skin or within an actinic keratosis, but they may also develop in burn scars or chronic inflammatory wounds. These lesions may

FIGURE 111.8. Squamous cell carcinoma of the hand secondary to exposure to arsenic in welding flux.

infiltrate widely. Metastasis to regional lymph nodes accounts for approximately 80% to 90% of metastatic cases. Distant sites, such as the lung, liver, brain, bone, and skin, account for the other 10% to 20%. Metastatic SCC portends a poor prognosis with a 10-year survival rate for regional lymph node disease of less than 20% and for distant disease of 10%.⁷²

Accurate assessment of the higher-risk cutaneous SCCs is handicapped because of the lack of large prospective studies using multivariate analysis. Nine variables, however, have been identified as prognostic risk factors by retrospective analysis. Factors that may determine a higher risk for local recurrence, extensive subclinical invasion, and metastasis are noted in Table 111.9.

FIGURE 111.9. Ulcerative squamous cell carcinoma.

Surgical Treatment of the Common Nonmelanoma Skin Cancers

A skin biopsy for diagnosis is important before treatment of any skin cancer. Fortunately, most NMSCs are small, low-risk lesions that respond with 90% to 95% cure rates to standard treatment techniques, including curettage and electrodesiccation, cryosurgery, radiation therapy, and surgical resection.⁷⁹ Many skin cancers can be removed with elliptical excisions. Margins for low-risk SCC range from 0.5 to 1.0 cm. Margins for low-risk BCC range from 0.3 to 0.5 cm. Mohs surgery should be considered for BCCs and SCCs that exhibit the higher-risk factors in Tables 111.8 and 111.9. If Mohs surgery is not available, section with careful frozen section control (with permanent section confirmation) is indicated. The fundamental oncologic principle of tumor clearance first and reconstruction second should be followed.

Mohs Surgery

Mohs surgery was developed by Frederick E. Mohs, a general surgeon from the University of Wisconsin, in the 1940s. Initially, a chemical fixative paste was applied to the skin to fix the tissue in situ; hence, the now outdated term *Mohs chemosurgery*. The fresh tissue technique, which omitted the chemical paste, was developed and refined in the 1970s. Mohs micrographic surgery is most useful for the treatment of higher risk NMSC (Tables 111.8 and 111.9). Mohs surgery is usually performed under local anesthesia in an outpatient Mohs surgical unit.^{80–82} After removal of all gross tumor, the surgeon excises a thin layer of tissue with 2- to 3-mm margins. The tissue is mapped, color-coded for orientation, and sent to the technician

FIGURE 111.10. Mohs micrographic surgical technique.

for frozen section processing. The specimen is flexible and flattened, with the beveled peripheral skin edge placed in the same horizontal plane with the deep margin. In this plane, both the deep and peripheral margins are examined in one horizontal cut by frozen section analysis with total (theoretically 100%) margin control. Good-quality frozen sections may be achieved only by a skilled and experienced Mohs histotechnician. The Mohs surgeon functions as both surgeon and pathologist. After histologic interpretation of the frozen section specimens, the precise anatomic location of any residual tumor can be identified and re-excised until all margins are tumor free (Fig. 111.10). The Mohs surgeon's ability microscopically to track subclinical tumor extensions results in the highest cure rate with maximal preservation of normal tissue. Soft tissue reconstruction can then be performed on the same day, after completion of Mohs surgical excision of the tumor (Fig. 111.11). A multidisciplinary approach involving Mohs, plastic, head and neck, and oculoplastic surgeons and radiation oncologists may be needed for extensive tumors. Mastering the Mohs technique is based on a steep learning curve that requires extensive training for optimal competence. Numerous 1- to 2-year Accreditation Council for Graduate Medical Education (ACGME) postgraduate fellowship training programs in procedural dermatology are available.

Based on a review of all studies from all disciplines since 1950, the 5-year cure rate for treatment of previously untreated primary BCC by Mohs surgery is 99%, versus 90% to 93% for all non-Mohs modalities, including standard surgical excision.⁸³ For previously treated recurrent BCC, the 5-year cure rates are 94% for Mohs versus 60% to 84% for non-Mohs modalities.⁸⁴ In general, Mohs surgery should be considered for NMSCs that are associated with a higher risk of recurrence after standard treatment and for tumors for which conservation of normal tissue is important. Risk factors for recurrence after standard

FIGURE 111.11. A: Patient with a 3 × 3 cm basal cell carcinoma on the right dorsal hand with mixed nodular and aggressive growth histologic pattern. B: Final Mohs surgery defect measuring 4.0 × 4.8 cm to the underlying tendon with preservation of tendon and nerve structures. Complete excision of the tumor required two Mohs stages (10 frozen sections). C: The defect was reconstructed immediately after achievement of clear margins under local anesthesia in the Mohs surgery unit using birhombic flap soft tissue reconstruction. D: Result 3 months after surgery.

treatment have been mentioned previously. Tumors for which maximal conservation of tissue may be important include tumors in the high-risk locations and tumors in young patients.

Adjuvant and Primary Radiation Therapy

Radiation therapy may be useful for primary treatment of low-risk NMSCs. In experienced hands, primary radiation therapy may also be useful for higher-risk tumors with high cure rates. For cutaneous SCC with many high-risk factors and for those with extensive neurotropism, adjuvant prophylactic radiation therapy to the primary site and the primary draining lymph nodes may decrease the risks of local recurrence and regional nodal metastasis. Prophylactic adjuvant radiation therapy should also be considered for highly aggressive, deeply invasive BCCs that exhibit extensive neurotropism.

Other Tumors of Interest

Hundreds of cutaneous tumors exist, and their description is beyond the scope of this chapter. Tumors that may be encoun-

tered by the surgeon for further management include Merkel cell carcinoma (MCC), sweat gland carcinoma, and DFSP.

MCC, or primary cutaneous neuroendocrine carcinoma, is an aggressive skin cancer with a higher overall mortality than melanoma (approximately 33% vs. 15%, respectively).⁹⁸ The incidence of MCC is low compared to other cutaneous malignancies (approximately 1,500 annually in the United States), but the number of cases has tripled over the last two decades.⁹⁹ While UV radiation and immunosuppression are considered important pathogenetic factors, recent findings suggest a virus (Merkel cell polyomavirus) as a contributing factor in the pathogenesis of MCC.¹⁰⁰ MCC most commonly occurs in older, white individuals, with only 5% diagnosed before age 50 years. The majority of tumors (90%) are located on sun-exposed skin, equally distributed between the head and neck and extremities. The remaining 10% are located on the trunk and buttocks. Primary MCC typically presents as a new-onset, growing, red or purple, dome-shaped or subcutaneous nodule, frequently mistaken for a cyst, lipoma, or BCC (Fig. 111.12). The most common location of metastasis is the draining lymph node basin, followed by distant skin, lung, central nervous system, bone, and liver.¹⁰¹ MCC is a dermal small blue cell tumor with positive immunohistochemical staining for

FIGURE 111.12. Merkel cell carcinoma.

cytokeratin-20 (CK-20) in a characteristic paranuclear dot-like pattern. Small cell lung cancer, another neuroendocrine carcinoma histologically indistinguishable from MCC and occasionally CK-20 positive, expresses thyroid transcription factor-1 (TTF-1), which is consistently absent in MCC.¹⁰² Newly proposed AJCC staging for MCC distinguishes stage I (primary tumor <2 cm without nodal disease), stage II (primary tumor ≥2 cm without nodal disease), stage III (nodal metastasis), and stage IV disease (distant metastasis). Five-year survival rates for stage I, II, and III are 81%, 67%, and 52%, respectively. Stage IV disease carries a dismal 11% 2-year survival rate.⁹⁸ The majority (70%) of patients with MCC present clinically with localized disease (stage I or II), 25% have palpable lymphadenopathy (stage III), and 5% present with distant metastases (stage IV).¹⁰¹ Multidisciplinary management of MCC is encouraged by the NCCN.^{103,104} Treatment consists of WLE with 1- to 2-cm margins. Adjuvant radiation therapy to the primary site should be considered and is recommended for stage II disease. SLNB with immunostaining using CK-20 is highly recommended for all primary MCC to stage the nodal basin and guide regional nodal therapy.^{103,105} Regional lymph node metastases can be treated by regional therapeutic lymphadenectomy and/or radiation therapy. Adjuvant radiation therapy to the regional nodal basin should be considered if SLNB is not performed or is thought to be false negative. For nonsurgical candidates, primary treatment of MCC with radiation therapy may also be considered.¹⁰⁶ Chemotherapy has failed to demonstrate a survival benefit in an adjuvant setting in the treatment of localized or regional MCC and should be reserved for distant metastatic (stage IV) disease.¹⁰⁷

Sweat gland carcinomas represent a broad scope of neoplasms with variable risk for local, regional, or distant metastasis, most commonly of eccrine or apocrine origin.¹⁰⁸ These are rare tumors (0.005% of skin malignancies) that have multiple histologic subtypes, giving rise to a diverse and confusing nomenclature. The aggressive types of sweat gland carcinomas have a propensity for both local recurrence and regional or systemic metastasis. Clinically, these tumors appear as indurated plaques, papules, or nodules commonly on the head and neck or extremities and are red, blue, pink, or skin colored. Histologic subtypes that are associated with a risk of regional lymph

node or systemic metastasis include aggressive digital papillary adenocarcinoma, hidradenocarcinoma, and eccrine carcinoma. Recommended treatments have included wide excision of the primary tumor with consideration of SLNB for high-risk lesions commonly based on size, mitotic rate, growth rate, or immunosuppression.¹⁰⁸ Postoperative radiation may also be considered as adjuvant therapy.

8 DFSP is a rare soft tissue sarcoma (1% of all soft tissue sarcomas) with a propensity for local recurrence rather than systemic metastasis. It is a spindle cell tumor that characteristically demonstrates immunoreactivity to CD34.^{109,110} Adults in their third to fifth decades are most commonly affected, but DFSP may occur in children or the elderly. These tumors appear as firm flesh-colored to dull red plaques that may be mistaken for keloids or hypertrophic scars. Although DFSPs may appear discrete, they characteristically demonstrate extensive subclinical involvement, which makes this sarcoma difficult to manage. Histologically, these sarcomas are identified by their fingerlike projections of spindle cells that likely account for tumor recurrence. Standard histologic processing makes it difficult to track these fingerlike projections. Treatment commonly consists of WLE with more comprehensive margin assessment or Mohs surgery, depending on patient and tumor factors. A multidisciplinary approach utilizing the expertise from several fields (Mohs surgery, surgical subspecialties, pathology) may be needed to achieve the goals of tumor excision and reconstructive repair. Radiation may also be beneficial in surgically unresectable cases.^{109,110} Imatinib mesylate has shown promising results in the treatment of unresectable or metastatic DFSP.¹¹¹

CHAPTER 112 ■ SARCOMAS OF SOFT TISSUE AND BONE

SANDRA L. WONG

KEY POINTS

- 1 Sarcomas are a rare and heterogeneous group of cancers that arise from mesoderm-derived elements such as muscle, fat, nerve/nerve sheath, cartilage, blood vessels, bone, and other connective tissue. They are distinguished from cancers of epithelial origin.
- 2 Clinical behavior and prognosis are largely defined by anatomic location, tumor grade, size, and completeness of surgical resection.
- 3 For extremity sarcomas, limb-sparing procedures are used to maximize functional outcomes. Radiotherapy is used for high-risk tumors to decrease disease relapse and improve survival.
- 4 Surgical resection is the cornerstone of treatment for intra-abdominal or retroperitoneal sarcomas. Complete resection may require en bloc resection of adjacent organs, most commonly of the kidney and colon.
- 5 The successful use of imatinib, a selective tyrosine kinase inhibitor, in the contemporary management of gastrointestinal stromal tumors is a paradigm for targeted molecular therapies.
- 6 Use of multimodality therapies including surgical resection, chemotherapy, and radiotherapy have dramatically improved outcomes for bone sarcomas such as osteosarcoma and Ewing sarcoma.

Sarcomas are a heterogeneous group of cancers that arise from mesenchymal cells, or mesoderm-derived elements, including muscle, fat, nerve/nerve sheath, cartilage, blood vessels, bone, and other connective tissue. Sarcomas of soft tissue and bone are considered two distinct categories. Though mesoderm-derived elements constitute nearly two thirds of the body's mass, sarcomas are relatively rare. In 2010, an estimate of just over 10,000 new cases of soft tissue sarcoma were expected to be diagnosed in the United States,¹ which accounts for less than 1% of all new cancers. Sarcomas also represent an extremely

heterogeneous group of cancers, but taken together, 5-year overall survival is about 50% to 60%.^{2,3} Anatomic location, tumor size, grade, and histopathology are important determinants of clinical presentation, treatment, and prognosis.

The Greek word “sarkoma,” meaning ‘fleshy excrescence,’ is the origin for the term *sarcoma*. As early as CE 130–200, these fleshy tumors were regarded as cancerous by Galen.⁴ With the evolution of light microscopy and cellular pathology, there was increasing recognition of soft tissue sarcomas. Sarcomas, then called “soft cancers,” were differentiated from

carcinomas by neuroanatomist Charles Bell as early as 1816. Virchow refined the definition of sarcoma as “new formations of connective tissue” and developed classifications according to microscopic features that separated sarcomas from carcinomas of epithelial origin. Modern foundations for the description and histogenic descriptions of sarcoma are attributed to the work of James Ewing, who over the course of his pathology career refined the classification of sarcomas, including the importance of grade in disease outcome.⁵

Multimodality therapies, including surgery, radiation, and chemotherapy, have been combined to improve local and systemic tumor control. Over the past few decades, a multidisciplinary approach has moved treatment options from radical amputation to limb-sparing procedures. As refinements in pathologic classification continue, so does progress in the use of treatment modalities. Modern molecular diagnostics are increasingly being translated to clinical practice, and tailored treatment options are being developed as the histologic diversity of soft tissue sarcomas is continually elucidated.

Epidemiology

Soft tissue sarcomas can occur in all age groups and are equally distributed between genders. Although the median age at diagnosis varies by histopathologic subtype, sarcomas are among the most common cancers that occur in children and young adults. Though sarcomas are relatively rare in the adult population, these tumors represent approximately 15% of pediatric malignancies and often occur in children younger than 5 years of age.⁶ Sarcomas can occur at any anatomic site, though most arise in the extremities and trunk (Fig. 112.1). Histopathologic subtype distribution is variable by anatomic site, and anatomic site influences treatment and outcomes (Fig. 112.2).

Although the vast majority of sarcomas arise spontaneously, there are some predisposing conditions to consider. Sarcomas are not thought to be the result of malignant degeneration of a long-standing benign lesion such as a lipoma. A traumatic incident may lead to the initial recognition of a mass, but there are no data to support the notion that antecedent trauma leads to the development of soft tissue or bony sarcomas. Clinical evaluation and subsequent workup, including biopsy if indicated, should be able to distinguish malignant growths from various benign posttraumatic lesions, such as myositis ossificans, which must be differentiated from an extraosseous osteogenic sarcoma.

Toxic exposures leading to the development of sarcoma are largely of historic interest. For example, industrial use of thorium dioxide (Thorotrast), arsenic, and vinyl chloride led to accumulation of toxins in the liver and were associated with

FIGURE 112.1. Classification of sarcomas by anatomic location. More than 50% of sarcomas are located in the trunk or extremities. RP/IA, retroperitoneum intra-abdominal sites. Visceral sites include gastrointestinal tract, gynecologic, and genitourinary tract tumors. From 7,527 cases at Memorial Sloan-Kettering Cancer Center, July 1982 to December 2007. (Courtesy of Murray F. Brennan, MD, Memorial Sloan-Kettering Cancer Center, New York, NY.)

the development of hepatic angiosarcomas. Various types of radiation have been implicated in the later development of sarcomas. For example, ingestion of luminous paint containing ²²⁶radium by factory workers led to the development of osteosarcomas. With the increasing use of external beam radiation in cancer treatment, there has been a noted increase in the modern incidence of sarcoma in patients treated with radiation for various malignancies. Following median latent periods of approximately 8 years (range 6–20 years), radiation-associated sarcomas are being increasingly diagnosed in previously radiated areas. Common radiation-associated sarcoma subtypes are malignant fibrous histiocytoma, fibrosarcoma, angiosarcoma, and leiomyosarcoma, and they are commonly, but not uniformly, high grade.^{7,8} Notably, with the advent of breast conservation therapy for breast cancer (lumpectomy and radiation therapy), there should be an appropriate index of suspicion for breast angiosarcomas with findings of skin changes on the breast (Fig. 112.3).

Several other predisposing conditions are known to be associated with the development of sarcoma. The classic Stewart-Treves syndrome was originally described in patients with lymphedema following radical mastectomy and radiation for breast cancer who then developed lymphangiosarcoma of the affected arm.⁹ Since then, long-standing extremity edema from other causes has also been linked to the development of lymphangiosarcomas. Kaposi sarcoma was previously an

FIGURE 112.3. Radiation-associated angiosarcoma. This 79-year-old woman developed skin changes on her breast 7 years after breast conservation therapy (lumpectomy and radiation therapy) for a 2 cm invasive ductal adenocarcinoma. Salvage mastectomy was performed.

uncommon cutaneous vascular tumor thought limited to elderly men of Mediterranean origin. In the early 1980s it became one of the first described opportunistic diseases associated with HIV infection. Though the incidence of HIV-associated Kaposi sarcoma has markedly declined with effective antiretroviral therapy, it remains an important cause of morbidity among HIV-infected patients and other immunosuppressed patients such as renal allograft recipients.^{10–12}

A genetic predisposition to sarcoma occurs in patients with neurofibromatosis type 1 (NF-1, or von Recklinghausen disease), and malignant peripheral nerve sheath tumors (MPNST) develop in an estimated 5% of patients over a lifetime.¹³ A genetic predisposition to desmoid tumors or desmoid fibromatosis is associated with familial adenomatous polyposis (FAP), or Gardner syndrome.^{14,15} Intra-abdominal and extremity desmoids are a common extracolonic manifestation of FAP and can be a source of increased morbidity in these patients following colectomy for the prevention or treatment of colon cancer.¹⁶

MOLECULAR BIOLOGY AND DIAGNOSTICS

Although the vast majority of sarcomas are sporadic, numerous genetic alterations are associated with both bone and soft tissue sarcomas.¹⁷ Better understanding of the molecular biology of sarcomas has revolutionized diagnosis of specific histopathologic subtypes and has elucidated potential pathways for targeted molecular therapy. One well-documented mechanism of sarcoma development is the inactivation of tumor suppressor genes. Retinoblastoma was known to be associated with a mutation in the retinoblastoma gene (RB1), a 13q chromosomal deletion. Investigation of the link between familial retinoblastoma and osteosarcoma led to the discovery that a genetic defect in RB1 also plays a role in the pathogenesis of sarcomas.^{18,19}

Another inherited defect of a tumor suppressor gene associated with soft tissue sarcomas is the Li-Fraumeni syndrome, caused by an inherited mutation in the p53 gene, a key growth-regulatory gene.²⁰ Germline mutations in affected patients are associated with high incidences of childhood rhabdomyosarcomas, breast cancer, brain tumors, lung cancer, and leukemias.²¹ p53 abnormalities may be present in as many as 60% of

osteosarcomas and malignant fibrous histiocytomas, as well as approximately 33% of other sarcomas.²² Several oncogenes that can induce malignant transformation and drive proliferation have also been associated with sarcoma development, including amplifications of N-myc, c-erbB2, and members of the *ras* family.²³

Cytogenetic aberrations have been recognized in several soft tissue sarcomas.¹⁷ Several histologic subtypes of sarcomas have each been found to have specific genetic alterations—usually simple karyotypes including fusion genes due to reciprocal translocations or specific point mutations (Table 112.1). These chromosomal translocations serve as powerful diagnostic markers and may be important in determining tumor biology and subsequent tumor behavior. For example, identification of the translocation of t(X;18)(p11;q11) can confirm the diagnosis of synovial sarcoma if there is any doubt of its histopathology. There are data to suggest that the SYT-SSX1 fusion transcript carries a worse prognosis than the SYT-SSX2 fusion transcript, with median survivals of 6.1 years and 13.7 years, respectively.^{24,25}

SOFT TISSUE SARCOMAS

Clinical Presentation

The most common presentation of a soft tissue sarcoma is that of an asymptomatic mass. Sarcomas tend to grow in a centrifugal fashion, pushing surrounding structures away rather than directly invading them. Such compression generally does not produce pain, swelling, or obstructive symptoms until the tumors become quite large. Because of surrounding anatomic structures, tumors of the extremities tend to be detected at a relatively smaller size, whereas tumors of the retroperitoneum are infrequently smaller than 10 cm at time of presentation.⁵ Even very large abdominal or retroperitoneal sarcomas present with nonspecific abdominal symptoms such as fullness, early satiety, or minor abdominal discomfort (Fig. 112.4). The differential diagnosis for a soft tissue sarcoma includes many types of benign lesions (e.g., lipomas, leiomyomas, neuromas) but also other malignant lesions (e.g., primary or metastatic carcinoma, melanoma, lymphoma).

In general, the vast majority of soft tissue masses tend to be benign, but concerning features that should prompt a higher index of suspicion for malignancy include large size (>5 cm), deep location (subfascial, intramuscular, intra-abdominal), variations in texture on examination, immobile nature or noted fixation to underlying structures, or changes to an existing lesion (increasing size or worsening compressive symptoms). No tumor markers for sarcomas exist, so serum blood work is generally not useful in the evaluation of soft tissue masses.

Diagnostic Imaging

Accurate radiologic imaging is critical in the diagnostic workup of sarcoma to provide information about the precise location and extent of the primary tumor. Computed tomography (CT) scans and magnetic resonance imaging (MRI) are the most important studies for evaluating the resectability of soft tissue sarcomas, providing definition of the primary tumor in relation to bone, muscle, neurovascular structures, and adjacent organs. Plain radiographs of bones and radionuclide bone scans rarely provide useful information regarding invasion of bone by the tumor. Both CT and MRI can provide critical information for treatment planning. Although MRI may be preferred for extremity sarcomas, CT is often the modality of choice for abdominal and retroperitoneal tumors. However, there appears to be no difference between high-quality CT and MRI in terms of ability to determine involvement of nearby structures, bone, or neurovascular structures.^{26–28}

TABLE 112.1**CYTOGENETIC ABNORMALITIES IN SOFT TISSUE SARCOMA SUBTYPES**

HISTOLOGIC SUBTYPE	CHROMOSOMAL TRANSLOCATION	FUSION GENE

FIGURE 112.4. Dedifferentiated liposarcoma of the retroperitoneum. This 51-year-old woman presented with only vague symptoms of abdominal fullness from a very large retroperitoneal mass. The CT scan demonstrates a heterogeneous soft tissue mass in the upper abdomen (A), which blends into a more fatty component (B) that encases the left kidney and displaces abdominal contents. She underwent radical resection en bloc left nephrectomy, distal pancreatectomy, splenectomy, left colectomy, and segmental resection of inferior vena cava.

FIGURE 112.5. Pulmonary metastasis. A noncontrasted CT scan of the thorax demonstrates a 1.1-cm noncalcified nodule consistent with pulmonary metastasis in the upper lobe of the right lung.

Imaging is also important as part of the extent of disease workup. Because sarcomas are known to metastasize predominantly to the lungs, directed chest imaging should be performed at time of diagnosis. Chest radiography (CXR) may be used, but CT scans are increasingly being used as the screening examination of choice for patients with high-grade lesions or tumors larger than 5 cm.²⁹ Any abnormal CXR must be followed by a CT scan for more detailed evaluation of potential pulmonary metastases (Fig. 112.5). CT of the chest, abdomen, and pelvis should be considered in any

patient with a myxoid liposarcoma of an extremity because this subtype often metastasizes to the abdomen or other “fat pads” such as the axilla.³⁰

MRI is the most commonly used imaging modality for extremity sarcomas.^{26,31} Sequencing routinely involves axial T2-weighted and precontrast/postcontrast T1-weighted images. Contrast enhancement with gadolinium is crucial for detecting and characterizing lesions with coronal, sagittal, and other reconstructions. This imaging modality can accurately delineate between muscle groups and distinguish among tumor and neurovascular structures (Fig. 112.6). Magnetic resonance angiography (MRA) can be performed if more accurate delineation of vascular structures is required for treatment planning.

Positron emission tomography (PET) scanning using fluoro-18-deoxyglucose also offers the potential for noninvasive analysis of tumor metabolism and has been shown to correlate with both tumor grade and response to treatment for many types of cancers.^{32–35} PET may be helpful in distinguishing between benign and malignant lesions and may be useful for assessing response to treatment.³⁶ However, its accuracy and potential for false-negative results are still incompletely defined so its use is not routine.

Diagnostic Biopsy

Properly performed biopsies are critical in directing a multimodality treatment approach. Image-guided techniques are increasingly being applied so that open biopsy is not mandatory. Fine-needle aspiration (FNA) is frequently used for the evaluation of enlarged lymph nodes, thyroid nodules, or breast masses. However, FNA often does not provide sufficient material for histopathologic diagnosis. Core-needle biopsy (CNB) is considered the initial procedure of choice for diagnosis of soft tissue sarcomas.³⁷ CNB retrieves sufficient material for immunohistochemical staining, and when necessary, for cytogenetic analysis or flow cytometry. Image-guided CNB, using either computed tomography (CT) or ultrasound (US), allows for the biopsy of deep masses that may not be easily palpable and can help target suspicious areas for better diagnostic value. An adequate sample

FIGURE 112.6. Extremity sarcoma. MRI demonstrates a 2-cm low-grade myxoid liposarcoma. **A:** Coronal reconstruction demonstrates location in the distal right thigh. **B:** Axial images show displacement of the popliteal vessels and vastus medialis anteriorly; the common tibiofibular nerve and biceps femoris laterally; and the semimembranosus and semitendinosus muscles medially.

from a viable area of sarcoma is required for definitive diagnosis and accurate grading.

Open surgical biopsy, or incisional biopsy, is uncommonly needed with increasing success of CNB. However, open biopsy should be considered when core-needle specimens yield nondiagnostic findings and if preoperative diagnosis is definitely required for treatment planning. Several important technical factors must be considered when performing an incisional biopsy. Incisions must be oriented along the long axis of extremities to facilitate definitive management. A transverse incision in the extremity often commits the patient to more extensive procedures than would be otherwise necessary, potentially compromising the ability to obtain clear margins with definitive limb-sparing procedures. Attempts to enucleate the sarcoma within its pseudocapsule are discouraged though excisional biopsy can be considered as the primary approach for small, superficial lesions.⁵

Pathologic Classification

Histopathologic designations of soft tissue sarcomas reflect an extremely heterogeneous group of tumors. Sarcomas are generally classified according to the tissues they mimic rather than the type of tissue from which the tumor arises. Some sarcomas have no recognizable normal tissue counterpart and are characterized by other distinguishing histologic features.^{5,38} The various types of benign and malignant soft tissue tumors are noted in Table 112.2. The development of specialized markers for identifying individual types of sarcoma has led to greater precision in their classification. Helpful immunohistochemical stains include the intermediate filaments (i.e., vimentin, keratin) and muscle markers (i.e., desmin, actin). More specific markers can be instrumental in diagnosis, such as myoglobin staining for rhabdomyosarcomas. In a small proportion of tumors (approximately 10% in most series), the tumor cells are so poorly differentiated that no specific histogenesis can be determined, and these may be designated as spindle cell sarcomas or pleomorphic sarcomas.

One of the most critical pieces of pathologic information for clinicians treating sarcoma patients is histologic grade. Histologic grade is assessed based on the degree of cellular atypia, the frequency of mitotic figures, and the presence or absence of spontaneous tumor necrosis. Although grading criteria have undergone numerous revisions over the years, in general, low-grade tumors have relatively little cellular atypia, few mitoses, and no tumor necrosis. High-grade tumors show a significant degree of necrosis in addition to atypia and frequent mitotic figures (Fig. 112.7). A consistently applied grading system discriminates between tumors with good prognosis (low grade) and those with poorer prognosis (high grade). In the past, a three-grade system has been used (low, intermediate, high), and until recently the American Joint Commission on Cancer (AJCC) used a classification system ranging from well-differentiated (G1) to undifferentiated (G4)^{39–41} tumors, though in 2010, that was changed to a three-tier system. There can be disagreement about grading schemas, and expert pathology opinion can vary from center to center.^{42,43} As such, it is important to take note of tumor classification when interpreting results from clinical trials or retrospective reports.⁴⁴ The metastatic potential for low-grade lesions is approximately 5% to 10% and up to 50% to 60% for high-grade tumors.² For lesions in which disparate areas exist, the highest grade encountered is generally used to categorize the tumor.

Staging

Because of the prognostic importance of staging, stage classification of the primary tumor is based on both clinical and histologic information. The usual TNM classification used by the AJCC⁴¹ for other solid tumors is modified to a GTNM system (Table 112.3) for soft tissue sarcomas. For the practical purposes of staging, well-differentiated and moderately differentiated tumors (grades 1 and 2) are considered together as low grade, whereas poorly differentiated and undifferentiated tumors (grades 3 and 4) are considered together as high grade.

TABLE 112.2

CLASSIFICATION

HISTOLOGIC CLASSIFICATION OF SOFT TISSUE TUMORS

■ CONNECTIVE TISSUE	■ BENIGN SOFT TISSUE TUMOR	■ MALIGNANT SOFT TISSUE TUMOR (SARCOMA)
Fat	Lipoma	Liposarcoma
Fibrous tissue	Fibroma	Fibrosarcoma
Skeletal muscle	Rhabdomyoma	Rhabdomyosarcoma
Smooth muscle	Leiomyoma	Leiomyosarcoma
Bone	Osteoma	Osteosarcoma
Cartilage	Chondroma	Chondrosarcoma
Synovium	Synovioma	Synovial sarcoma
Blood vessels	Hemangioma Hemangiopericytoma	Angiosarcoma
Lymphatics	Lymphangioma	Lymphangiosarcoma
Nerve	Neurofibroma	Neurofibrosarcoma
Mesothelium	Benign mesothelioma	Malignant mesothelioma
Histiocytes	Benign fibrous histiocytoma	Malignant fibrous histiocytoma
Uncertain		Ewing sarcoma Alveolar soft parts tumor Epithelioid sarcoma

FIGURE 112.7. Histologic grading of sarcomas. Photomicrographs demonstrate the appearance of different grades within the same histologic subtype. A: Well-differentiated liposarcoma (lipoma-like) of the retroperitoneum with noted few atypical lipoblasts. B: High-grade, dedifferentiated liposarcoma of the retroperitoneum with highly atypical lipoblasts. (Courtesy of David R. Lucas, MD, University of Michigan, Ann Arbor, MI.)

The primary tumor is categorized according to size (<5 cm = T1, >5 cm = T2) and depth relative to the fascia (entirely above the fascia, or superficial = a; invading or entirely below the fascia, or deep = b). Because depth of tumor seemed to add significant prognostic information, this distinction was added to the 1998 edition of the AJCC staging system. One series of 215 patients with superficial extremity sarcomas documented a 10-year survival rate of 85% although 53% of tumors were high grade and 25% of tumors were 5 cm or larger.⁴⁵ Though the cutoff between small and large tumors is 5 cm, tumors larger than 10 cm seem to have an even worse prognosis.⁴⁶ When 316 patients with soft tissue sarcoma were grouped into four subgroups (<5 cm, 5–10 cm, 10–15 cm, and >15 cm) each subgroup had a distinct prognosis (84%, 70%, 50%, and 33%, respectively).⁴⁷

For nonmetastatic sarcomas, the AJCC staging system is clinically useful because it assigns patients into groups with clearly different prognoses (Fig. 112.8). Nodal metastasis of soft tissue sarcomas is rare (less than 5% of cases), with the exception of a few histologic subtypes for which the incidence of nodal involvement may be between 10% and 20%. These subtypes include angiosarcoma, embryonal rhabdomyosarcoma, epithelioid sarcoma, synovial sarcoma, and clear cell sarcoma.⁴⁸ By far the most common site of metastasis is the lungs though metastases to other sites do occur. Unlike other solid organ tumors, when node involvement occurs in sarcomas, it conveys essentially the same prognosis

as distant metastatic disease and therefore is classified as stage IV disease.

Treatment

Principles of Surgical Resection. Complete surgical resection remains the cornerstone of treatment for soft tissue sarcomas. Performing a wide excision of the tumor with negative margins is the goal of resection with curative intent. Compartmental excision, or enucleation, usually results in inadequate resection and should be avoided. Technical aspects of resection must take into consideration the anatomic location and extent of disease. Often, soft tissue sarcomas are surrounded by a zone of compressed reactive tissue that forms a pseudocapsule. Care should be taken to avoid entry into the tumor and pseudocapsule during the course of dissection. Enucleation commonly results in microscopically positive margins, and patients evaluated after such resections should undergo re-resection, even if they have no clinical or radiographic evidence of residual tumor, recognizing that anatomic location may preclude effective clearance of margins even with a second operation.

Metallic clips placed in the tumor bed following resection can help define the limits of resection and aid in planning of future treatment. Suction drainage catheters are routinely used to obviate postoperative seroma formation following resection of extremity or truncal sarcomas. Drains should be placed

FIGURE 112.8. Survival rates according to the American Joint Committee on Cancer (AJCC) staging system. Patients with soft tissue sarcoma were categorized by tumor depth, grade, and size. 3A designates stage III tumors of 5 to 10 cm, and 3B designates stage III tumors greater than 10 cm in size. TABLE 112.3**CLASSIFICATION**

AMERICAN JOINT COMMISSION ON CANCER (AJCC): GTNM CLASSIFICATION AND STAGE GROUPING OF SOFT TISSUE SARCOMAS

■ CLASSIFICATION	■ DESCRIPTION
TUMOR GRADE	
GX	Grade cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated
PRIMARY TUMOR	
TX	Primary tumor cannot be assessed
T0	No evidence of a primary tumor
T1	Tumor <5 cm in greatest diameter
T1a	Superficial tumor
T1b	Deep tumor
T2	Tumor <5 cm in greatest diameter
T2a	Superficial tumor
T2b	Deep tumor
LYMPH NODE INVOLVEMENT	
NX	Regional lymph nodes cannot be assessed
N0	No known metastases to lymph nodes
N1	Verified metastases to lymph nodes
DISTANT METASTASIS	
MX	Presence of distant metastasis cannot be assessed
M0	No known distant metastasis
M1	Known distant metastasis
STAGE GROUPING	
Stage I	G1–2, T1a, N0, M0 G1–2, T1b, N0, M0 G1–2, T2a, N0, M0 G1–2, T2b, N0, M0
Stage II	G3–4, T1a, N0, M0 G3–4, T1b, N0, M0 G3–4, T2a, N0, M0
Stage III	G3–4, T2b, N0, M0
Stage IV	Any G, Any T, N1, M0 Any G, Any T, N0, M1

close to the incision so that the site can be included in a post-operative radiation field and to minimize the extent of proximal involvement if amputation ever becomes necessary. A unique characteristic of sarcoma is the lack of metastasis to regional lymph nodes. If regional lymphadenopathy is discovered in conjunction with a diagnosis of sarcoma, therapeutic lymphadenectomy can be considered since clearance of disease may be associated with improved outcomes.^{48,49} In selected patients with clinically negative node examination, there may be a role for sentinel lymph node biopsy to identify occult micrometastatic disease.⁵⁰

Taken together, sarcomas of the upper and lower extremities and trunk make up most soft tissue sarcomas. Large truncal tumors may require reconstruction with a myocutaneous

flap or prosthetic materials if resultant defects cannot be closed primarily (Fig. 112.9). Largely of historic interest now, radical amputations were once the mainstay of treatment for extremity sarcoma, but modern surgical approaches involve limb-sparing procedures (Fig. 112.10), which maximize functional outcomes. As recently as the 1970s, more than 50% of all soft tissue sarcomas of the extremity were treated with radical amputations. The accepted standard of care changed after a group at the National Cancer Institute, led by Rosenberg,⁵¹ published the results of a randomized trial of limb-sparing resection plus adjuvant radiation therapy compared to amputation, finding no differences in disease-free survival rates (71% vs. 78%, respectively) and the overall survival rates (83% vs. 88%, respectively) at 5 years. This trial demonstrated that amputation was

FIGURE 112.9. Chest wall sarcoma. A 20-year-old man with a 7.5-cm right posterior chest wall epithelioid sarcoma involves the 11th and 12th ribs as demonstrated on CT scan (A) and on physical exam (B). Chest wall resection was performed, including a portion of diaphragm. Resulting chest wall defect (C) was repaired using prosthetic mesh (D).

not mandatory, and in 1985, a National Institute of Health consensus statement recommended limb-sparing procedures for most patients with high-grade extremity sarcomas.⁵² Radical amputations, such as hemipelvectomy, hip disarticulation or forequarter amputation, are now reserved for patients who are not suitable candidates for limb-sparing approaches, usually because of extent of disease, bony or joint invasion, or for otherwise unsalvageable recurrence after previous limb-sparing surgery (Fig. 112.11). There is no improvement in survival with this approach under these circumstances.⁵³

3 Acceptance of multimodality therapy has led to the ability to perform wide excisions while preserving function when treating extremity or truncal soft tissue sarcomas.^{5,54,55} Judicious use of radiation has allowed for the sparing of major neurovascular structures, though if necessary, arteries and/or veins can be resected en bloc with the tumor and subsequent reconstruction can be done with autologous or prosthetic graft materials. In cases of neurologic compromise, customized adjuncts from experienced physical medicine departments can help restore reasonable function. For instance, resultant foot drop from peroneal neuropathy can be managed with an ankle-foot orthotic and gait training. In some cases, resection should be planned in conjunction with a plastic surgeon to provide complex soft tissue reconstruction with microvascular

free flaps if the size of defect following resection prohibits primary closure.

Adjuvant and Neoadjuvant Therapies. The role of external beam radiotherapy is best defined by a trial comparing limb-sparing surgery alone with limb-sparing surgery with adjuvant radiation, showing improved 10-year local recurrence rates with radiation. In high-grade sarcomas, the recurrence rate was 0% versus 22%, respectively, though no significant effect on overall survival was appreciated.⁵⁶ Certainly, in the setting of involved surgical margins that could not otherwise be resected, adjuvant radiation therapy is associated with improved local control.^{3,57}

There is controversy regarding the optimal use of radiation in the preoperative setting compared to the postoperative setting for extremity and truncal sarcomas. Radiation in the adjuvant setting with either external beam radiation or brachytherapy has long been the standard approach.³ Typically, the entire surgical bed and drain sites are included in the field, along with wide margins around the sarcoma. Hemoclips marking the site of resection can be placed at the time of resection to help with radiation planning. It is important that an individual approach be taken with each patient since radiation can result in severe complications when used inappropriately (Table 112.4). For

FIGURE 112.10. Wide excision involves removal of the tumor with a margin of normal tissue. If necessary, major vascular structures or nerves may be resected.

FIGURE 112.11. A: Radical amputations for extremity sarcomas include one joint above the most proximal extent of tumor. Now largely of historic interest, tumors of the proximal thigh or buttock were previously routinely treated with hemipelvectomy. B: Although limb-sparing procedures are now done whenever possible, amputation may be necessary for certain cases. This 60-year-old woman had high-grade angiosarcoma of the right leg with extensive satellite metastases extending above her knee. She required above-knee amputation.

TABLE 112.4

COMPLICATIONS

COMPLICATIONS OF TREATMENT FOR EXTREMITY SARCOMA

TREATMENT MODALITY	COMPLICATION	COMMENT
Surgical resection	Wound complications Seroma/hematoma Inadvertent damage to neurovascular structures	
Radiation	Fibrosis Edema Pathologic fracture Delayed wound healing/wound complications	Prophylactic intramedullary nailing may be considered. Greater incidence with preoperative radiation treatment.
Chemotherapy		
Doxorubicin	Myelosuppression Cardiotoxicity (arrhythmia, heart failure)	Combination therapy may have additive toxicities. Alopecia and nausea/vomiting are common side effects of these chemotherapy agents.
Ifosfamide	Myelosuppression Neurotoxicity Nephrotoxicity	Baseline echocardiogram and/or MUGA is mandatory.

example, the entire circumference of the extremity should not be irradiated because massive lymphedema may result. Severe fibrosis, necrosis, fractures, and contractures can also occur with focused treatment and result in impaired function. Wound healing may be compromised in patients undergoing adjuvant radiation, and in selected cases, use of rotational flaps for coverage can prevent or minimize chronic wound healing problems.⁵⁸ Similarly, radiation must be used judiciously in sensitive areas since nearby visceral structures are exquisitely sensitive to higher doses of radiation. Dose-limiting toxicity must be considered when recommending such therapies.

An alternate approach to adjuvant radiation is brachytherapy,⁵⁶ which involves the placement of multiple catheters or seeds in the tumor resection bed to administer iridium¹⁹² (Fig. 112.12). Unlike the several-week course needed to complete external beam radiation, a course of brachytherapy can be completed in a few days. In theory, brachytherapy produces less radiation scatter in critical areas, decreasing toxicity while obtaining equivalent functional outcome.⁵⁹ However, brachytherapy requires special equipment and can involve technically complex treatment planning by an experienced radiation oncologist. From a therapeutic standpoint, brachytherapy and external beam radiation appear to be equivalent when properly adminis-

tered. There is increasing interest in the use of intraoperative radiation therapy (IORT), though its effectiveness is unproven. If IORT is used, it is currently done in conjunction with a planned external beam boost dose.⁶⁰

Patients with high-risk (large [>10 cm], high-grade) extremity sarcomas should be considered for preoperative treatment with chemotherapy or with chemoradiation since overall local control rates are disappointing with postoperative radiation alone.⁵⁴ Local control rates were considerably higher when large tumors were treated before surgery, and in some cases, tumors initially considered unresectable without amputation shrank sufficiently to permit limb-sparing resection. There are several benefits of preoperative radiation. With the tumor in situ, there tends to be a smaller overall treatment volume and the theoretical advantages of more effective radiation because it is being delivered to an undisturbed tumor bed. There is also the potential benefit of decreased seeding during the course of resection and improved margin status because the radiation may shrink the tumor's pseudocapsule and render it relatively acellular. However, there is one major disadvantage to preoperative radiation and that is its detrimental effect on wound healing. Several studies, including a large randomized trial in Canada,⁶¹ demonstrated significant differences in major wound complications with preoperative versus postoperative radiation (35% vs. 17%, respectively). Longer-term outcomes seem acceptable, even boasting similar or improved outcomes in terms of functional results.⁶² Some groups have used an intraoperative or postoperative boost dose of radiation to the resection bed if margins are involved.

Increasing data support the use of resection alone for selected patients; those who have small (<5 cm), low-grade tumors seem to have acceptable local control and excellent long-term survival without radiation if wide margins are obtained at time of resection.^{63,64} Most patients undergoing surgical excision may be candidates for additional radiation therapy because of high risk for recurrence, though its role in lower- or intermediate-risk patients is somewhat undefined, and the so-called therapeutic ratio of risk and benefits to radiation treatment must be carefully considered. Validated prognostic tools may be helpful for individual patients weighing the benefits of available treatment options. Kattan et al.⁶⁵ developed a nomogram to help better predict individual risk for 12-year disease-specific mortality in sarcoma patients using multiple prognostic factors simultaneously.

FIGURE 112.12. Adjuvant brachytherapy for extremity sarcoma. Brachytherapy catheters are shown in a resected tumor bed.

For extremity sarcomas, the importance of pathologically negative margins must be emphasized. Although differing widths of margins have been called optimal, it is generally agreed that 1 to 2 cm are adequate, but that microscopically clear margins may be sufficient. Involved margins, along with age, recurrent presentation, and fibrosarcoma or MPNST subtypes, significantly increase the risk of local recurrence.^{3,66} Patients presenting with involved margins following the index operation should be offered re-resection to obtain surgical clearance of margins. Several studies have shown no compromise in survival if complete resection is achieved with a second operation.⁶⁷ Interestingly, it is unclear if local recurrence predisposes to subsequent distant metastasis or if margin status is merely a proxy for aggressive disease.^{66,68}

Since the main cause of death in patients with soft tissue sarcoma is distant metastatic disease, continued efforts have been made to develop effective systemic therapies.^{5,69} Postoperative adjuvant chemotherapy has been controversial because risk of adverse toxic effects may not be outweighed by the relatively low response rates and lack of durable results. The histologic subtypes of sarcoma vary in their responsiveness to chemotherapy. For example, osteogenic sarcoma, rhabdomyosarcoma, and Ewing sarcoma (the pediatric sarcomas) have had high rates of success with multimodality treatments including adjuvant chemotherapy.⁵⁴ Unfortunately, most randomized trials are underpowered to detect modest differences in survival, and promising response rates reported in smaller nonrandomized clinical trials are not duplicated in subsequent larger randomized trials. In general, adjuvant chemotherapy is not ever indicated for patients with low-grade sarcomas and patients with small sarcomas of higher grades. Initial interest in adjuvant chemotherapy for extremity soft tissue sarcoma was piqued by a randomized trial reported by Rosenberg et al.,⁷⁰ which demonstrated an improvement in disease-free and overall survival with adjuvant doxorubicin, cyclophosphamide, and high-dose methotrexate. After a longer follow-up period (median follow-up 7.1 years), however, both disease-free and overall survival were not statistically significant.⁷¹

Over the years, single agents as well as combination chemotherapy regimens have been used in the adjuvant treatment of soft tissue sarcomas. Two of the more active agents include doxorubicin and ifosfamide. However, multiple randomized trials of postoperative chemotherapy have not demonstrated an improvement in disease-free or overall survival with intermediate- or long-term follow-up though there was a trend toward chemotherapy in many studies.^{54,72–74} The Sarcoma Meta-analysis Collaboration evaluated the effect of adjuvant doxorubicin-based chemotherapy in 1,568 patients from 14 trials.⁷⁵ Although the time to local and distant recurrences, as well as recurrence-free survival, were significantly better in the treatment group, an overall survival advantage was not observed (HR 0.89, $p = 0.12$). Because of the rarity of disease and heterogeneity of tumor characteristics, most studies are too small to provide adequate power for testing responses in specific histologic subtypes. In general, many regimens have combined two of the most active agents, doxorubicin (or other anthracycline) and ifosfamide, and results from a randomized trial did show improved disease-free survival and overall survival; distant relapse rates were not different, however.⁷⁶ Outside of clinical trials, doxorubicin and ifosfamide combination therapy is commonly used for high-risk, primary extremity, and truncal sarcomas in the adjuvant setting. Newer regimens with promising results include the combination of gemcitabine and docetaxel, which was initially discovered to be active in heavily pretreated uterine leiomyosarcomas and is currently being considered for use in that subtype as well as in high-grade undifferentiated pleomorphic sarcomas and other high-risk subtypes.^{77–79}

One potential advantage of upfront systemic chemotherapy is the ability to assess tumor response in situ. By seeing whether the tumor responds to the chemotherapy, both radiologically

and pathologically, it may be possible to spare patients prolonged therapy if they have not shown a response, or to continue therapy postoperatively if there is response. However, data from a trial of preoperative doxorubicin and ifosfamide-based chemotherapy conducted by the European Organisation for Research and Treatment of Cancer (EORTC) and the National Cancer Institute of Canada did not demonstrate any survival benefit compared to surgery alone.⁸⁰ Some agents such as gemcitabine may have chemosensitizing properties,⁸¹ making preoperative chemoradiation strategies attractive. Based on current evidence, neoadjuvant chemoradiation, either concurrent or sequential, should be offered only to selected high-risk patients on clinical protocol.⁸² It is important to follow patients on neoadjuvant therapy closely since tumor progression occurs in approximately 30% of patients.^{83,84}

Commonly used measures of radiologic response to treatment may not be good surrogate endpoints for treatment response.³⁶ The pathologic correlations of treatment-induced necrosis or histologic response to therapy with clinical outcomes have also not been well defined in soft tissue sarcoma.⁸⁵ Some patients who have a clinical or pathologic response to chemotherapy may have improved local control and decreased distant disease-free survival, but no overall survival advantage.⁸⁶ In other cases, lack of measurable response did not seem to predict significant differences in event-free endpoints.⁸³ These issues must be carefully considered in the design of future trials.

Alternative approaches to standard systemic therapy have been attempted with limited success. For example, preoperative radiation therapy in combination with intra-arterial doxorubicin chemotherapy initially showed good local control, but results could not be duplicated in subsequent randomized trials and treatments were associated with high morbidity.^{87,88} Regional chemotherapy administered via hyperthermic isolated limb perfusion has been attempted for advanced extremity sarcomas. Extracorporeal circulation allows the delivery of drug concentrations 10 to 20 times higher than with systemic delivery, and a European study showed a limb-salvage rate of 71% for unresectable extremity sarcomas using melphalan and tumor necrosis factor- α .^{89,90} However, this technique is uncommonly used in the United States and usually reserved for highly selected patient populations. Hyperthermia in combination with systemic chemotherapy is being evaluated for high-risk extremity sarcomas, but long-term data have not yet been reported.⁹¹

RETROPERITONEAL AND INTRA-ABDOMINAL SARCOMAS

Management of intra-abdominal (visceral) and retroperitoneal sarcomas deserves special consideration since specific anatomic location may dictate workup and subsequent management. The grouping of visceral sarcomas generally includes tumors of the gastrointestinal tract and gynecologic organs, and less commonly, genitourinary organs. Location often precludes early diagnosis, unless the mass is found incidentally. Though some patients have noted increased abdominal girth, an abdominal mass can be appreciated with focused physical examination, but it is uncommonly the presenting complaint. Typically, vague symptoms of mass effect intra-abdominally trigger a medical evaluation. Neurovascular symptoms related to compression or invasion can occur and manifest as paresthesia, dysesthesia, weakness, and swelling or varicosities in the lower extremities.

Complete history and physical examination should exclude signs and symptoms of lymphoma (e.g., B-symptoms such as fevers and night sweats) and presence of scrotal masses concerning for testes cancer. Serum laboratory testing can be helpful if lymphoma (e.g., elevated lactate dehydrogenase [LDH]), germ-cell tumors (e.g., elevated beta-human chorionic gonadotropin

FIGURE 112.13. Biopsy can be helpful in the workup of retroperitoneal masses. **A:** CT scan shows a retroperitoneal mass encasing the IVC and aorta. **B:** Image-guided biopsy is demonstrated here. Pathology confirmed a diagnosis of large B-cell lymphoma.

[B-HCG] or alpha-fetoprotein [AFP]), or adrenal tumors (e.g., cortisol levels or adrenocorticotrophic hormone [ACTH]) are in the differential diagnosis. High-quality cross-sectional imaging with CT or MRI is critical for diagnosis and treatment planning. Use of oral and intravenous contrast defines the extent of primary disease and the relationship of the tumor to nearby structures. Chest imaging should be obtained to assess for presence of pulmonary metastases. Hepatic involvement is the second most common site of distant spread in intra-abdominal and retroperitoneal sarcomas, so a CT scan that includes the proper contrast phasing for examination of the liver should be done.

For large tumors, preoperative image-guided biopsy can almost always be performed by experienced interventional radiologists (Fig. 112.13). However, preoperative biopsy is not mandatory^{5,92} if management would not be altered by findings. Use of biopsy is reserved for cases in which a diagnosis of sarcoma is in question or if neoadjuvant approaches are being considered for large, high-grade lesions or lesions that are locally advanced and potentially unresectable. Complete resection is the treatment of choice for intra-abdominal (visceral) and retroperitoneal sarcomas whenever possible. Only complete resection is associated with long-term survival benefit, with retroperitoneal liposarcomas being a possible exception.^{93,94} For retroperitoneal sarcomas, median survival for those with an incomplete resection is similar to those who were

observed (unresectable)⁹⁵ (Fig. 112.14). In general, incomplete resection should be considered only for palliation of intractable symptoms. Although successful palliation may be achieved in carefully selected patients, aggressive tumor biology limits the ability to maintain sustained relief of symptoms.⁹⁶

To attain complete removal of the sarcoma, en bloc resection of nearby structures should be considered when necessary. Resectability is more a function of location than of size, grade, or histologic subtype. Common reasons for unresectability include distant metastasis, peritoneal metastasis, extensive multifocality, and prohibitive vascular involvement. Though sarcomas do not uniformly invade other structures, involvement of vascular structures or mesentery (mesocolon) may lead to resection of solid organs or bowel that may not be directly involved. When nephrectomy may be necessary, it is important to assess bilateral renal function with preoperative contrast scanning. Concomitant nephrectomy, when necessary, is associated with comparable outcomes for retroperitoneal sarcomas overall.⁹⁷ Commonly resected organs include the following: kidney, colon, adrenal gland, pancreas, and spleen⁹⁸ (Table 112.5). For tumors located in the pelvis, it may be necessary to perform en bloc resection of the colon/rectum, bladder, and uterus. When vascular structures limit complete resection of tumor, resection with ligation or reconstruction of vessels must be considered if technically feasible (Fig. 112.15).

FIGURE 112.14. Kaplan-Meier plot of disease-specific survival for patients with retroperitoneal sarcomas treated at Memorial Sloan-Kettering Cancer Center. Disease-specific survival is 103 months in patients who underwent complete resection of retroperitoneal sarcomas, compared to 18 months in those who had an incomplete resection or just observation. (Reproduced with permission from Lewis JJ, Leung D, Woodruff JM, et al. Retroperitoneal soft-tissue sarcoma: analysis of 500 patients treated and followed at a single institution. *Ann Surg* 1998;228(3):355–365.)

Even when surgical resection is possible and complete gross resection is achieved, margin status is often compromised by constraints of visceral anatomy. A transperitoneal approach allows for excellent exposure and facilitates en bloc resection with early control of the vascular supply to the tumor. Even with aggressive surgical management, local recurrence rates range

from 40% to 70% for high grade tumors.^{17,99} Unlike in extremity sarcomas, local progression is associated with decreased survival. Difficulty obtaining negative margins and high recurrence rates support a possible role for multimodality treatments.

However, the benefits of radiation for extremity sarcomas have not been similarly appreciated for retroperitoneal sarcomas, and no improvement in disease-free intervals have been noted.¹⁰⁰ Large field sizes and the dose-limiting toxicity of abdominal viscera limit the utility of postoperative radiation, and preoperative radiation warrants consideration. The major advantage of preoperative radiation is the displacement of small bowel and other structures by the in situ tumor. Similar to preoperative radiation for extremity tumors, a possible advantage in the abdomen/retroperitoneum is that the radiation may prevent later seeding of tumor cells because radiation is administered to tumor and surrounding peritoneum. With the advent of conformal technology, or intensity-modulated radiation therapy (IMRT), further selective application of radiotherapy may be possible with minimal toxicity.^{101,102} The role of chemotherapy, either in the preoperative or postoperative setting, is unproven for intra-abdominal and retroperitoneal sarcomas.^{103,104} Several trials of postoperative adjuvant chemotherapy do not show any benefit for patients with retroperitoneal sarcoma, and in one series, treated patients fared worse than those not receiving chemotherapy.¹⁰⁵ In one trial of an aggressive multimodality approach, there was an improvement in locoregional control but no overall survival advantage and significant toxicity from

FIGURE 112.15. Inferior vena cava (IVC) leiomyosarcoma. **A:** CT scan demonstrates a $9.2 \times 6.4 \times 4.4$ cm mass within the lumen of the retrohepatic IVC. **B:** Photograph of the gross specimen. Cross-sectional view from the superior aspect of the specimen demonstrates the extensive filling of the lumen with multilobulated tumor. **C:** Photomicrograph demonstrating intraluminal high-grade leiomyosarcoma with nuclear atypia and pleomorphism. the chemotherapy and radiation therapy.¹⁰⁶ Though some histologic subtypes, such as leiomyosarcoma, pleomorphic sarcoma, or myxoid/round cell liposarcoma, may be relatively more responsive to systemic treatments, a paucity of data exist to guide appropriate use of therapy.

Special consideration is also given to complete resection with functional preservation in head and neck sarcomas and genitourinary sarcomas. As is true of sarcomas in other anatomic locations, histologic grade and size adversely affect prognosis for head and neck sarcomas.¹⁰⁷ Resections with negative margins may not require adjuvant radiotherapy treatments. Grade, size, location, and histologic subtype predict disease-specific survival for genitourinary sarcomas.¹⁰⁸ Regional relapse is influenced by margin status so radical resections are necessary. Unfortunately, recurrences are not uncommon and may be difficult to control due to anatomic location.

RECURRENT OR METASTATIC DISEASE

About two thirds of soft tissue sarcoma recurrences occur in the first 2 years after diagnosis and treatment, though recurrences may occur at any time.¹⁰⁹ Recurrences may be classified as locoregional or distant. Though no standardized follow-up regimens exist, routine history and physical examination (clinical follow-up) and interval chest imaging are recommended for the first 2 to 3 years. Site-specific imaging guidelines are less clear. Directed cross-sectional imaging studies are helpful if location of tumor precludes early detection of recurrence on clinical evaluation alone. Of course, the choice of imaging study depends on availability, cost, and anatomic site being examined. MRI of the extremity or trunk can help detect locoregional recurrences when they are relatively small. CT scans may be useful for detection of intra-abdominal or retroperitoneal recurrences that would otherwise be undetectable. However, there is no evidence that earlier detection improves survival for retroperitoneal sarcomas,⁹⁵ so a less aggressive imaging schedule may be appropriate.

If chest radiography is used, abnormal findings should be followed with a CT scan of the chest. Low-grade lesions infrequently metastasize in the absence of local recurrence though they can recur locally up to 20 years after original resection. For high-grade lesions, surveillance should be directed toward detecting recurrence and metastatic disease. Patients with locally recurrent or even metastatic sarcomas can be considered for surgical resection if tumor biology supports potential cure or effective palliation with removal of known disease. Recurrent disease, especially within the abdomen or retroperitoneum, becomes more difficult to treat with each recurrence.¹⁰⁹

If a recurrence is suspected, a biopsy should be performed to confirm diagnosis and review histologic subtype as well as tumor grade, with reference to the original tumor if possible. In the absence of distant disease, an aggressive surgical approach is warranted with the goal being the same as with a primary sarcoma: control of the tumor and preservation of as much function as possible. For patients who were initially treated with surgery alone and who failed locally, multimodality treatment with repeat resection, radiation, and sometimes chemotherapy is associated with survival rates close to those of previously untreated patients.^{110–112} Independent predictors of survival in patients with locally recurrent extremity soft tissue sarcomas include histologic grade, size of recurrent disease, and recurrence-free interval.¹¹³

The most common site of distant metastatic disease is the lung, and its presence is not detectable by symptoms. Again, CT is the preferred imaging modality, though its very high sensitivity for detecting pulmonary nodules as small as 2 mm decreases its specificity.^{114,115} Occasional patients have liver, bone, or central nervous system metastases though these sites

FIGURE 112.16. Kaplan-Meier plot of disease-specific survival for patients with pulmonary metastases treated at Memorial Sloan-Kettering Cancer Center. Patients treated with complete resection had a median survival of 33 months. Patients who underwent incomplete resection or who did not undergo resection had median survival of 16 months and 11 months, respectively. (Reproduced with permission from Billingsley KG, Burt ME, Jara E, et al. Pulmonary metastases from soft tissue sarcoma: analysis of patterns of diseases and post-metastasis survival. *Ann Surg* 1999;229(5):602–610.)

of disease are relatively uncommon. Once diagnosed, metastatic disease is best approached with systemic chemotherapy, either as a single agent or with combination treatments. Pulmonary metastases are the most common form of distant disease, and metastasectomy in carefully selected patients seems to improve outcomes. Taking patient selection into account, resection of pulmonary metastases in combination with radiation and/or chemotherapy may improve outcomes compared to resection alone^{116,117} (Fig. 112.16).

GASTROINTESTINAL STROMAL TUMORS (GIST)

Another subtype of sarcoma that deserves separate consideration is gastrointestinal stromal tumor (GIST). Prior to modern molecular diagnostic techniques, these tumors were likely to have been considered leiomyosarcomas based on histologic features.¹⁷ It is now known that GIST are differentiated from GI leiomyosarcoma based on lack of well-differentiated smooth muscle cells. GIST are composed of more primitive mesenchymal cells and originate from the interstitial cell of Cajal, which functions within the GI autonomic nervous system. Immunohistologic diagnosis is made via expression of KIT (CD 117) cellular markers (Fig. 112.17). KIT overexpression is usually related to mutations in the *KIT* gene, although *PDGFR-α* mutations can also result in KIT overexpression in approximately 3% to 5% of GIST. KIT-negative GIST have been reported, though tumor genotyping should be done to either *KIT* or *PDGFR-α* mutations even with negative immunohistochemistry for KIT.¹¹⁸

The *KIT* protooncogene encodes for KIT protein, a transmembrane glycoprotein receptor with an intracellular tyrosine kinase domain. Binding of the KIT ligand induces dimerization and autophosphorylation of KIT, activating a cascade of intracellular signaling that results in cell proliferation and tumorigenesis. A gain of function mutation in KIT occurs in up to 90% of GIST¹¹⁹ and results in ligand-independent (constitutive) activation of tyrosine kinase function.¹²⁰ KIT mutation is found in 90% of GIST, and the most frequent sites of mutation

FIGURE 112.17. Strong and diffuse kit immunoreactivity is demonstrated in a gastrointestinal stromal tumor. (Reproduced with permission from Kelsen DP, Daly JM, Kern SE, et al. *Gastrointestinal Oncology: Principles and Practice*. Philadelphia: Lippincott Williams & Wilkins; 2002.)

are found in exon 11 (70%) or exon 9 (10%), whereas rare mutations are found in exon 13 or exon 17.¹²¹ Mutation status may affect prognosis, though it is not routinely tested for.

The exact incidence of GIST has been difficult to determine because of its relatively new recognition as a distinct pathologic entity. Swedish epidemiologic data estimate 14.5 cases per million, which translates to an annual U.S. incidence of 4,000 to 5,000 cases.¹²² GIST are nearly all sporadic, but they have occurred in association with hereditary syndromes such as von Recklinghausen disease and the Carney triad, and familial germline mutations have been identified. Clinical presentation can be indolent: Most patients have nonspecific symptoms such as nausea, emesis, or abdominal discomfort. Infrequently, GIST can rupture or bleed, leading to a more emergent presentation. GIST are most commonly found in the stomach (50%–60%), with 30% to 40% of tumors in the small bowel, 5% in the colon or rectum, and 5% in the esophagus. Rarely, GIST develop within the mesentery, omentum, or retroperitoneum. Most GIST are found in adults older than 40 years of age, with a median age of 60 years. Tumors found in children or young adults are considered a separate entity since pediatric GIST have a more epithelioid histology and wild-type KIT or PDGFR- α genotype.¹²³

Complete surgical resection is the treatment of choice for GIST, but recurrences are common and 5-year survival following resection of a localized tumor is approximately 50%.¹²⁴ Recurrences are common and thought to occur at 18 to 24 months from the time of the index operation. Lymph node dissection is not warranted because GIST very rarely metastasize to regional nodes. Treatment of GIST has been revolutionized with the development of imatinib mesylate (Gleevec), an orally administered, molecularly targeted agent that is a selective tyrosine kinase inhibitor. The proof of concept for this treatment paradigm was demonstrated in 2000 when a patient with diffuse metastatic disease achieved a near-complete metabolic response¹²⁵ on PET and with 75% reduction in tumor size at 8 months and histologic evidence of myxoid degeneration and lack of mitotic activity. Contemporary use of imatinib in patients with metastatic GIST results in approximately 80% partial response or stable disease, and imatinib is considered appropriate first-line treatment of metastatic disease (Fig. 112.18).

The use of imatinib in the neoadjuvant or adjuvant setting is still under investigation.¹²⁶ It is reasonable to consider the use of imatinib for large or borderline resectable lesions prior to surgical resection. Postoperative use of imatinib has been suggested for high-risk tumors, including tumors that are

FIGURE 112.18. ¹⁸F-FDG-PET scan showing response of metastatic GIST to imatinib mesylate. This patient presented with primary disease in the small bowel and synchronous metastatic disease in the liver. The scan at presentation (left) compared to the one obtained after 3 weeks of therapy (right) shows decrease in size of tumors and decreased ¹⁸F-FDG uptake in both the small bowel and liver tumors consistent with a good response to imatinib. The patient eventually went on to complete surgical resection. (Reproduced with permission from Gold JS, DeMatteo RP. Combined surgery and molecular therapy: the gastrointestinal stromal tumor model. *Ann Surg* 2006;244(2): 176–184.)

greater than 5 to 10 cm in size or contain more than 5 mitoses per 50 HPFs (high-powered fields). Risk-stratification must be approached with care; other factors that need to be considered include location of tumor and mutation status. Isolated surgical resection of recurrences has limited utility, and imatinib should be considered in addition to resection.

DESMOID TUMORS/ DESMOID FIBROMATOSIS

Desmoid tumors warrant separate notation in the discussion of soft tissue tumors because of their distinct biologic behavior.^{14,127} Desmoid tumors, or aggressive deep-seated fibromatosis, are part of a rare group of fibrous tissue proliferations that have no propensity for metastasis but tend to be locally aggressive. The natural history of desmoid tumors is poorly understood and not well defined. Clinical behavior and, therefore, recommended treatments are often dictated by anatomic site. Location of tumors can limit therapeutic options and result in significant morbidity with or without surgical resection.

Desmoid tumors are uncommon with an estimated incidence rate of 2 to 4 cases per million per year. The median age of diagnosis is 35 years, range 16 to 79 years. Desmoids are slightly more common in women than men. Desmoid tumors are classically described as an abdominal wall tumor that develops in young women during the postpartum period.¹²⁸ However, desmoids can occur at any site in the body, and three main anatomic sites are described: (i) trunk or extremity, (ii) abdominal wall, and (iii) intra-abdominal (bowel and mesentery). Fibromatosis is usually sporadic but can be associated with familial adenomatous polyposis.

Desmoids are characterized by a monoclonal fibroblastic proliferation arising from muscular or aponeurotic structures. On gross examination, the tumors appear firm and smooth with a surrounding pseudocapsule. However, microscopically, the tumor characteristically extends beyond this pseudocapsule with

fibrous septae of tumor extending radially. Desmoid tumors had previously been classified as an unchecked reactive process rather than a neoplastic process, but uniform patterns of X-chromosome inactivation seems to confirm tumors of clonal composition.¹²⁹ There appears to be an increased estrogen receptor- β , but not estrogen receptor- α , expression in 80% of desmoid specimens.¹³⁰ These findings lend some support for the treatment of tumors with adjuvant agents such as tamoxifen.

Tumors tend to be located deep in the muscles or along fascial planes, such as at a point of muscular insertion. Patients will usually present with a greater than 5-cm, localized, firm mass with an indolent pattern of growth, which can be minimally painful. Intra-abdominal presentations can be associated with mass effect, intestinal obstruction, or mucosal ischemia. Desmoid tumors are notoriously infiltrative, and margins are microscopically involved in a significant number of patients.

Complete resection is considered the best course of treatment, though resection is sometimes constrained by anatomic boundaries. For intra-abdominal tumors, extensive association with the mesentery limits the extent of resection and could predispose to significant morbidity and ultimately, mortality due to bowel involvement. Resection of large abdominal wall tumors often requires prosthetic reconstruction of the resulting defect. Ability to accomplish complete resection at the first attempt defines likelihood of recurrence, so it is important to have a sufficient preoperative suspicion of fibromatosis and to be circumspect in surgical technique. Positive margins do not inevitably lead to recurrent disease, just as patients with a complete microscopic resection are often found to have local recurrences.¹³¹ There are no data to support the use of radiation therapy in the adjuvant setting following a complete surgical resection. The utility of radiation in the setting of positive resection margins is thought to be quite minimal given the difficulty in predicting risk of recurrence in these patients. Several systemic treatment regimens have been used in the past and in present practice with varying results.

BONE SARCOMAS

Various primary bone tumors are well described (Table 112.6). The vast majority (>70%) of bone malignancies represent metastasis from another site or are of hematologic origin (lymphoma or myeloma). Primary bone cancers, however, are relatively rare types of cancer and account for less than 0.2% of all cancers, with only an estimated 2,380 new cases in 2008.¹ The

three main types of bone sarcomas are osteosarcoma (which arises from bone), chondrosarcoma (which arises from cartilage), and Ewing sarcoma (which has an undefined origin). As with soft tissue sarcomas, a GTNM staging system is used by the AJCC⁴¹ (Table 112.7). Modern multimodality treatment approaches have been associated with excellent outcomes, including cures for most osteosarcoma cases.

Osteosarcomas are the most common primary bone tumors. Osteosarcomas occur most commonly around the knee, either in the distal femur or proximal tibia, but they can be encountered in any bone (Table 112.8). Osteosarcomas originate in the metaphyseal ends of the involved bone. Although there are eleven known variants of osteosarcoma, classic osteosarcoma accounts for nearly 80% of incident cases. This tumor commonly occurs in children and young adults. Other important variants include osteosarcoma associated with Paget disease,¹³² which corresponds to a later peak in incidence at 60 years of age. Other well-described etiologies of osteosarcoma include prior radiation or history of retinoblastoma.¹³³ Classic osteosarcoma is of intramedullary origin and is high grade. Osteosarcoma patients are at high risk for metastatic disease; metastases to the lung are the most common, though bony metastases are not uncommon. Low-grade variants do exist, and these less aggressive tumors are usually parosteal or periosteal in location. Elevated serum alkaline phosphatase and lactate dehydrogenase is associated with reduced disease-free survival and overall survival rates.

Chondrosarcomas are typically classified as either primary or central tumors arising from previously normal-appearing bone, or secondary or peripheral tumors that develop from pre-existing benign cartilage lesions.^{134,135} The secondary or peripheral lesions are usually low grade and infrequently metastasize. Chondrosarcomas usually occur in middle-aged or elderly people, though they can appear at any age. Ewing sarcomas are broadly considered a family of small round cell neoplasms and include the following subtypes: Ewing sarcoma, primitive neuroectodermal tumor (PNET), and extrasosseous Ewing sarcoma. Most Ewing sarcomas occur in adolescents and young adults, but they can develop in older individuals. These tumors may arise in soft tissues as well as bone, and most commonly occur in the femur, pelvic bones, and chest wall (Askin tumor).

Clinical Presentation

A painful mass is the most common presenting complaint with an extremity osteosarcoma, though symptoms of chondrosarcoma

CLASSIFICATION

HISTOLOGIC CLASSIFICATION OF BONE TUMORS

■ TISSUE CATEGORY	■ BENIGN TUMOR	■ MALIGNANT TUMOR (BONE SARCOMA)
Bone	Osteoid osteoma	Osteogenic sarcoma
	Osteoblastoma	Parosteal osteogenic sarcoma
Cartilage	Osteochondroma	Periosteal osteogenic sarcoma
	Endochondroma	Chondrosarcoma
	Chondroblastoma	Mesenchymal chondrosarcoma
Fibrous lesions	Benign fibrous histiocytoma	Malignant fibrous histiocytoma
	Giant cell tumor	Adamantinoma
	Fibrous dysplasia	Fibrosarcoma
Vascular	Aneurysmal bone cyst	Angiosarcoma
Other	Glomus tumor	Hemangiopericytoma
		Ewing sarcoma

TABLE 112.7**CLASSIFICATION**

AMERICAN JOINT COMMISSION ON CANCER (AJCC): GTNM CLASSIFICATION AND STAGE GROUPING OF BONE SARCOMAS

■ CLASSIFICATION	■ DESCRIPTION
TUMOR GRADE	
GX	Grade cannot be assessed
G1	Well differentiated
G2	Moderately well differentiated
G3	Poorly differentiated
G4	Undifferentiated
PRIMARY TUMOR	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤8 cm in greatest dimension
T2	Tumor >8 cm in greatest dimension
T3	Discontinuous tumors in the primary bone site
LYMPH NODE INVOLVEMENT	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
DISTANT METASTASIS	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
STAGE GROUPING	
Stage IA	G1–2, T1, N0, M0
Stage IB	G1–2, T2, N0, M0
Stage IIA	G3–4, T1, N0, M0
Stage IIB	G3–4, T2, N0, M0
Stage III	Any G, T3, N0, M0
Stage IVA	Any G, any T, N0, M1a
Stage IVB	Any G, any T, N1, any M
	Any G, any T, any N, M1b

may be quite mild. Tumor location in the axial skeleton may also be associated with a more insidious presentation. Limitation of motion is often present when the tumor arises in proximity to a joint. Patients occasionally present with a pathologic fracture of the involved bone. Plain radiographs of the affected area often suggest a diagnosis. High-grade osteosarcomas lead to rapid destruction of bone evidenced by cortical destruction and demonstrate periosteal reaction with new bone formation; an extensive, poorly defined destructive bony lesion, often with an extraosseous component is often evident (Fig. 112.19). Ewing sarcomas have a classic “onion skin” periosteal reaction, and underlying bone often appears mottled. Primary or central chondrosarcomas show cortical destruction and calcification. Further radiologic evaluation with MRI (or CT scan) provides excellent detail of the anatomic extent of tumor and aids operative planning. Chest imaging should be used to determine if there is metastatic disease. Evaluation with radionuclide bone scanning and/or PET scans may also be useful.¹³⁶

After the radiologic evaluation establishes the extent of the bony lesion, diagnostic biopsy should be performed. Either

CNB or open biopsy techniques can be used. Placement of the incision should be carefully planned to avoid jeopardizing subsequent options for a limb-sparing procedure. Consideration should also be given to stabilization techniques if there is risk of pathologic fracture during treatment.

TABLE 112.8

DISTRIBUTION OF ANATOMIC LOCATIONS OF OSTEOSARCOMA

■ ANATOMIC SITE	■ PERCENTAGE (%)
Lower extremity	83
Upper extremity	9
Other (pelvis, shoulder, vertebrae)	7

FIGURE 112.19. Plain radiograph of the femur showing a high-grade osteosarcoma. The tumor is an ill-defined destructive lesion with an extensive soft tissue involvement. The Codman triangles (*arrows*) indicate periosteal reaction, which are characteristic, but not pathognomonic, of osteosarcoma.

Cytogenetic analysis for evaluation of the t(11;22) translocation should be done if Ewing sarcoma is suspected.¹⁷ Presenting features associated with poor prognosis in Ewing sarcoma include elevated serum lactate dehydrogenase levels, fever, anemia, large tumor volume, mutation in p53 or deletion of p16/p14ARF, and pelvic location. Most patients have at least micrometastatic disease at presentation, and bone marrow biopsy can be considered because it is a common site of distant disease.

Treatment

Standard treatment for Ewing sarcoma involves combination chemotherapy, followed by surgical resection. Regimens have evolved over time and currently involve some combination (or all) of the following agents: ifosfamide, cyclophosphamide, etoposide, doxorubicin, and vincristine.^{137–139} Investigations continue to define the trade-offs between survival benefit and toxicity of high-dose combination chemotherapy.¹⁴⁰ Adjuvant radiation can be considered or used as definitive treatment in some cases. Most patients will receive additional chemotherapy in the postoperative period as well. The aggressive use of multimodality therapy has led to excellent outcomes for patients with localized disease over time. Five-year survival rates have improved from 44% in the 1970s to 68% in the 1990s. Even outcomes with advanced disease at presentation have improved dramatically, increasing from 16% to 39% over the same time period.¹⁴¹

Surgical resection is the definitive treatment for most chondrosarcomas (Fig. 112.20). Intracompartmental lesions can be considered for intralesional resection with wide margins. Radiation can be considered as an adjuvant therapy, but chemotherapy is generally not very effective. If lesions are unresectable, radiation may be considered as a possible definitive treatment modality.

FIGURE 112.20. Chondrosarcoma recurrence. A 60-year-old man had previously undergone resection of a low-grade chondrosarcoma of the left pelvis, necessitating resection of the left iliac bone. After many local bony recurrences, he was found to have an extraskeletal site of disease. On the CT scan, adjacent to the remaining bone, there is a 4.4 × 3.6 cm soft tissue mass (*arrow*), which contains dystrophic calcifications. Recurrent disease was completely resected.

Historically, patients with clinically localized osteosarcoma treated by surgery alone had a 5-year survival rate of approximately 20%. Adjuvant systemic chemotherapy after surgery has generally improved that figure up to 55% to 70% in most randomized trials.^{142–146} Contemporary protocols that incorporate preoperative chemotherapy into the regimen have been associated with event-free survival rates of up to 70%.¹⁴⁷ The following agents have shown to be active, and regimens have used differing combinations of those agents: doxorubicin, cisplatin, ifosfamide, high-dose methotrexate. Progressive disease carries a poor prognosis. Disease relapse should be treated with further chemotherapy and resection if possible.

Extremity osteosarcomas are ideally treated with limb-sparing approaches when possible to maximize functional outcomes. Limb-sparing operations include complete removal of the affected bone and soft tissues. Various reconstructive techniques are available after resection of an extremity osteosarcoma. Autografts (such as vascularized or nonvascularized fibular grafts), cadaver allografts, and sophisticated endoprostheses can be used. Because the osteosarcoma population includes many children who continue to grow, modular prostheses that can periodically be expanded are increasingly being used.

CHAPTER 113 ■ PLASTIC AND RECONSTRUCTIVE SURGERY

DAVID L. BROWN, STEVEN R. BUCHMAN, PAUL S. CEDERNA, KEVIN C. CHUNG, EDWIN G. WILKINS, AND WILLIAM M. KUZON, Jr.

KEY POINTS

- 1 Because all open wounds are contaminated, the designation of a wound as “infected” should be contingent on the physical examination findings of local inflammation: erythema, pain, swelling, fluctuance, purulence, and loss of function.
- 2 Once a wound has been fully evaluated, the treatments should be designed to achieve specific goals. In order of greatest priority, these goals are (a) preventing complications resulting from the wound, (b) preserving or restoring critical functions, (c) achieving wound closure, and (d) restoring aesthetics.
- 3 Skin grafts are classified as either split thickness, where the epidermis and a portion of the dermis are harvested, or full thickness, where the epidermis and the entire dermis are harvested.
- 4 The rediscovery of the musculocutaneous perforator as a predominant vascular supply to the skin in many areas of the body has led to the wide use of musculocutaneous flaps. These flaps derive their inflow from a major muscular artery. Perforators emanating vertically from the muscle surface supply the skin overlying the muscle.
- 5 A variety of operative procedures have been described for breast reconstruction following mastectomy. These approaches can be categorized as implant based, autogenous (natural) tissue, and “hybrid” procedures.
- 6 A variety of autogenous (natural) tissue options have been described for postmastectomy breast reconstruction. Currently, the most commonly performed of these procedures is the transverse rectus abdominis myocutaneous flap.
- 7 The absolute indications for replantation (i.e., situations in which replantation should always be attempted) are (a) thumb amputation, (b) multiple finger amputations, (c) pediatric population amputations, and (d) midhand, wrist, or distal forearm amputations.
- 8 Rigid skeletal fixation, revascularization using vein grafts, and immediate wound coverage are crucial factors in successful limb salvage.
- 9 Aesthetic surgery requires meticulous attention to detail, careful patient selection, rigorous procedural planning, and precise execution of technically challenging procedures. If patients are carefully selected and their goals are realistic, then the chances for a successful outcome are good. However, if a patient is poorly selected or they have unrealistic goals, then a technically successful operation with an aesthetically pleasing outcome may be a dismal failure in the eyes of the patient.
- 10 Patients who smoke are at a significantly increased risk for developing postoperative complications, including skin flap necrosis, infection, or wound dehiscence, and are consequently instructed to quit prior to undergoing elective aesthetic surgery.
- 11 A cleft lip deformity can be bilateral or unilateral and is considered complete if it extends into the nose and incomplete if it does not. The cleft lip can extend into the gum partially or completely through the alveolus, creating a bony defect. The cleft lip deformity affects the nose as well as the lip, and therefore both of these structures must be addressed in the reconstruction of the deformity.
- 12 Craniosynostosis is defined as the premature fusion of one or more of the cranial sutures. The child afflicted with craniosynostosis displays abnormalities in the size and shape of the cranial vault. Virchow's law proposes that the growth of the skull will be restricted in the direction perpendicular to a synostosed suture while compensatory growth occurs in a parallel direction.

Plastic and reconstructive surgery can be defined as a discipline that addresses problem wounds using a diverse array of non-surgical and, especially, surgical therapies. In this definition, the term *problem wounds* is taken in the broadest sense; plas-

tic surgeons treat traumatic, congenital, developmental, and even psychological wounds. Perhaps it is this latter aspect of plastic surgery that most fully sets it apart from other surgical specialties:

TABLE 113.1 COMPLICATIONS**THE SPECTRUM OF PLASTIC SURGERY**

Aesthetic surgery
Burns: acute and reconstructive surgery
Craniofacial surgery
Cutaneous and soft tissue oncology
Hand and upper extremity surgery
Head and neck oncology
Microvascular surgery
Maxillofacial and orthognathic surgery
Peripheral nerve surgery
“General” reconstructive surgery
Face (ear, lip, nose, eyelid)
Breast
Trunk
Lower extremity

We restore and make whole those parts which nature or ill fortune have taken away, not so much to delight the eye but to buoy up the spirit of the afflicted.

—Gaspere Tagliacozzi, 1597

In more concrete terms, plastic surgery is an approach to surgical problems. Plastic surgeons operate “from the top of the head to the tip of the toes,” and they envision themselves as surgical innovators. Plastic surgeons have been instrumental in the development of microvascular surgery, craniofacial surgery, head and neck reconstruction, nerve grafting, and even renal transplantation.¹ Although the field of plastic surgery can be arbitrarily divided into “cosmetic” surgery (surgery to improve the appearance of a normal phenotype) and “reconstructive” surgery (repair of damaged anatomy or an abnormal phenotype), in many circumstances, both functional reconstruction and aesthetic improvement are paramount. Plastic surgery is truly “general surgery,” with a broad and growing list of subspecialties (Table 113.1).

PRINCIPLES OF MANAGEMENT FOR PROBLEM WOUNDS

Regardless of the etiology or location of a wound, the principles of management are universal and can be embodied by a straightforward algorithm:

1. Evaluate and, if possible, eliminate the factors contributing to the presence of the wound.
2. Control or optimize the wound prior to closure.
3. Close the wound using the simplest method, unless specific factors mitigate a more complex approach.

Although it is the nature of surgeons to focus on the technical details of operative procedures, the first two steps in this algorithm are most critical for the successful reconstruction of problem wounds. This algorithmic approach allows plastic surgeons to treat diabetic foot ulcers, infected sternotomy wounds, major defects after composite resection of the head and neck, pressure ulcers, lower extremity wounds after open tibial fractures, venous stasis ulcers, and other difficult defects with a high degree of success. *This rational approach is the core of plastic surgery.* In plastic surgery there is no one-to-one correlation between a surgical problem and a specific operation. There is no “right” way to reconstruct a given defect, and a spectrum of options must be considered for every recon-

structive problem. Selecting the best option for a given patient is the challenge.

Evaluation of Problem Wounds

The evaluation of patients with difficult wounds is best approached by considering local and systemic (or intrinsic and extrinsic) contributing factors for each phase of the workup. In the history, local factors of importance include the mechanism that resulted in the wound, symptoms such as pain or loss of function, the time course and progression of the wound, any previous nonsurgical or surgical treatments for the wound, and any history of previous injury, irradiation, malignancy, or other local factors that contributed to the presence of the wound. The history should also uncover systemic factors that impair wound healing, including immunosuppression (e.g., chemotherapy, immune deficiencies), medical conditions known to impair healing (e.g., diabetes, renal failure), medications (e.g., steroids, cyclosporin A), cigarette smoking, and general debility (e.g., nutritional deficiencies, old age).

The physical examination of patients with problem wounds should be focused on local and systemic signs that affect wound healing. For the wound itself, the location, size, depth, exposure of deep or vital structures, presence of necrotic material, presence of foreign bodies, or signs of any neoplastic processes should be carefully noted. Because all open wounds are contaminated, the designation of a wound as “infected” should be contingent on the physical examination findings of local inflammation: erythema, pain, swelling, fluctuance, purulence, and loss of function. Physical examination should be the primary criterion for the diagnosis of local wound infection; surface swabs indicating the presence of pathogenic bacteria do not correlate with clinically significant infection.² In addition to the wound itself, surrounding tissue should be examined for signs of injury (e.g., actinic changes), previous irradiation, arterial or venous insufficiency, lymphedema, loss of sensation, and dermal thinning (e.g., aging, steroid therapy). For all wounds on an arm or leg, a careful neurovascular examination for the entire limb is mandatory. In addition to the local examination, a focused systematic physical examination is mandatory in patients with problem wounds. Systemic signs of infection (e.g., fever, hypotension) are of particular importance. Obesity is a major risk factor that impairs wound healing. The general physical examination should focus on the systemic factors that affect wound healing as noted previously. Table 113.2 lists some of the local and systemic factors that impair wound healing; history and physical examination are the principal modalities for diagnosing these problems.

Laboratory examinations can be invaluable in the management of problem wounds. However, laboratory tests are often misused in wound patients, and a rational, evidence-based approach is necessary to efficiently utilize this expensive resource. Again, the local-systemic paradigm is useful in determining which laboratory examinations are warranted.

For local evaluation, as already mentioned, wound swabs can be valuable for surveillance of the flora contaminating a wound but should not be used as a trigger to initiate therapy for wound infection. Wound biopsy and quantitative bacteriology have proved valuable in the management of burns and chronic wounds.^{3,4} Bacterial loads in excess of 10^5 /g tissue indicate contamination at a level that precludes skin graft take and jeopardizes wound closure of any kind. The use of quantitative cultures, however, is not justified for most acute or uncomplicated chronic wounds. In general, quantitative cultures are reserved for “high stakes” wounds, where a failure of closure on the initial attempt may leave an unreconstructable situation with grave consequences, such as amputation or death. Wound biopsies can be invaluable for diagnosing invasive burn wound infection and are preferred over quantitative

TABLE 113.2 CLASSIFICATION**LOCAL AND SYSTEMIC FACTORS THAT AFFECT WOUND MANAGEMENT**

LOCAL FACTORS	SYSTEMIC FACTORS
Infection	Immune deficiencies
Local malignancy	Distant malignancy
Foreign bodies	Diabetes mellitus
Local toxins	Cigarette smoking
Radiation	Chemotherapeutic agents
Ischemia	Hereditary healing disorders
Venous insufficiency	Nutritional deficiency
Lymphatic insufficiency	Old age
Repetitive trauma	Uremia
Reduced sensation	Glucocorticoid therapy, immunosuppressive agents

culture for this purpose.⁵ The presence of bacteria in the deep dermis on biopsy is highly correlated with the risk of systemic sepsis in burn patients. Bone biopsy demonstrating bacteria within the bone is the preferred test for making the diagnosis of osteomyelitis. Standard radiographs are most useful for diagnosing and delineating acute fractures and are much less useful in the setting of chronic, open wounds. Ultrasound, computed tomography (CT) scan, or magnetic resonance imaging (MRI) may be useful for delineating fluid collections, necrotic tissue, or inflammation in selected circumstances. In contrast, radionuclide bone scans have little role to play in patients with open wounds or fractures. In the face of an open wound or recent fracture, a “hot” bone scan (even a triple-phase bone scan) is not specific for osteomyelitis and has little value. Therefore, obtaining bone scans in patients with suspected sternal osteomyelitis after recent midline sternotomy, in pressure sore patients with exposed bone, or in other patients with open wounds overlying exposed bone is unwarranted. Under these circumstances, bone biopsy is preferred for making a diagnosis of osteomyelitis and for determining the responsible pathogen; MRI is preferred for delineating the extent of bony involvement. Magnetic resonance angiography (MRA) or standard angiography may be indicated if vascular insufficiency is suspected or if a free-tissue transfer is planned.

The use of systemic laboratory investigations should be limited to specific indications; “routine” blood work is not required for patients with acute or chronic wounds. White blood cell differential counts and blood cultures can confirm the diagnosis of systemic infection. Serum albumin and transferrin determinations may be valuable in determining nutritional status. A greatly elevated erythrocyte sedimentation rate can help confirm the diagnosis of osteomyelitis. Other laboratory tests to confirm the diagnosis and severity of associated medical conditions may be justified for specific indications.

Treatment of the Problem Wound

- Once a wound has been fully evaluated, the treatments should be designed to achieve specific goals. In order of greatest priority, these goals are (a) preventing complications resulting from the wound, (b) preserving or restoring critical functions, (c) achieving wound closure, and (d) restoring aesthetics. Again, each of these goals may require specific local or systemic interventions.

Preventive Treatment. The preventive measures that should be taken for patients with open wounds depend on the setting. For an acute laceration, tetanus prophylaxis should be considered. For patients with pressure sores, a strict adherence to pressure-relief protocols and an assessment of nutritional status take priority. In wounds caused by human or animal bites, prophylactic antibiotics are warranted. In addition, any associated medical conditions that are contributing to the wound must be aggressively optimized. It is the responsibility of the surgeon to ensure that a patient with a wound does not develop a complication from that wound and that the patient does not develop more wounds from the same mechanism. This is of particular importance in bedridden, obtunded, or paralyzed patients, in whom it should be possible to completely prevent pressure sores with proper nursing care.

Preservation of Function. Preserving joint motion must always be considered for patients with open wounds of the extremities. Aggressive physiotherapy to maintain or improve joint motion can be instituted in the presence of an open wound. Splinting should be used to minimize joint contractions and any plans for wound closure should include measures to maintain joint function. In the case of facial defects, especially if facial paralysis is present, oral competence and the maintenance of eye protection should weigh heavily into any reconstructive plan. Function takes precedence over form in the reconstructive algorithm.

Nonsurgical Therapy. After careful consideration of preventive measures and the preservation of critical function, a strategy for wound closure can be formulated. The basic tenet is: “débride dirty wounds, close clean wounds.” Therefore, the first step in wound closure is achieving control of the wound by eliminating necrotic debris and controlling any infection present. Nonsurgical therapies are used in conjunction with surgical therapy to achieve a clean wound. The mainstay of local, nonsurgical therapy is the use of wound dressings. It is beyond the scope of this chapter to review the wide range of options available to dress wounds. Recent articles contain a contemporary review of this topic.^{6–8} However, the basic principle is to employ débriding dressings for dirty wounds and occlusive dressings for clean wounds. The most commonly employed débriding dressing is the “wet-to-dry” dressing. Gauze made damp with normal saline, weak acetic acid, weak bleach, or various other solutions is applied to the wound. Over a period of hours, evaporation dries the dressing, which becomes slightly adherent to the wound surface. When the dressing is removed, necrotic debris is pulled off with the dressing, but healthy tissue is left behind. Wet-to-dry dressings work through *mechanical débridement*, and the most important component of their use is how often they are changed. Wet-to-dry dressings must be changed a minimum of twice per day; they should not be “soaked” off to reduce patient discomfort because this technique completely defeats their purpose. Enzymatic dressings have also been used to débride wounds, but their use can be limited by patient tolerance to the pain they cause. Débriding dressings are indicated for infected wounds and wounds containing necrotic debris.

If a wound is “clean,” meaning that it does not contain necrotic debris and has an acceptable bacterial load, a dressing that maintains a moist wound environment to encourage wound healing should be used.⁸ For many simple wounds, allowing a scab to provide the moist healing environment or the application of a nonadherent sterile dressing is all that is required. In the case of more complex wounds, occlusive dressings that maintain a moist environment to maximize wound healing are preferred. Options include hydrocolloid dressings, alginate dressings, and various hydrogels. Again, occlusive dressings must not be used on infected or dirty wounds. For many wounds, judicious application of hydrocolloid dressings may allow closure by secondary intention in a reasonable period of time.

Under some circumstances, it is appropriate to use antibiotic dressings. Burn wounds are most commonly dressed with silver sulfadiazine or mafenide Sulfamylon (Bertek Pharmaceuticals, Inc., Research Triangle Park, North Carolina) dressings. The low toxicity and excellent antibiotic properties of elemental silver have led to the development and widespread use of wound dressings containing nanocrystalline silver. Acticoat (Smith & Nephew, London, UK) is particularly useful for the management of large burn wounds and for dressing skin grafts applied to chronic wounds.^{9,10} In general, however, antibiotic dressings are not required for clean wounds, even if they are chronic.

Last, it should be noted that we are entering a new era of nonsurgical wound management. A rapid advance in our understanding of wound healing has led to the development of growth factor therapy, cellular therapy, and new physical modalities for the treatment of chronic wounds.⁶ Although recombinant platelet-derived growth factor appears to be a useful adjunct to the dressing regimen for pressure sores and diabetic foot ulcers,^{11,12} there is general agreement that exogenously administered growth factors currently play a limited role in the management of acute and chronic wounds.¹³ Similarly, laboratory data point to the potential for the use of stem cells as a modality to treat difficult wounds, but cellular therapy for clinical wounds is still largely investigational.^{6,14}

A bigger clinical impact has been realized from tissue-engineered dressings and skin substitutes.^{15,16} Integra (Integra Life Sciences Corp., Plainsboro, New Jersey), a bilaminar skin substitute composed of a collagen matrix base with a silicone rubber barrier layer, has proven extremely useful in the management of complex wounds. Integra is most useful for burn wounds and wounds where a poorly vascularized base precludes immediate skin grafting. While the silicone membrane serves as a barrier and maintains a moist environment, the collagen matrix supports the ingrowth of vascularized granulation tissue. Integra is now an integral part of the management of burn wounds, with the silicone layer providing a temporary barrier function that allows excision of eschar when autograft supply is limited.¹⁵ In poorly vascularized wounds, the ingrowth of vascularized tissue allows skin grafting at a second operation. That is, this strategy converts a complex wound, requiring a flap reconstruction, to a much simpler wound that can be managed with skin grafting. Integra has proven to be of considerable utility in the management of wounds of the scalp resulting from the excision of skin cancers where bare skull is exposed in a previously irradiated field. Integra placement supports the development of a vascularized base and has allowed many such wounds to be closed with skin grafts.¹⁷ Likewise, the management of wounds of the hand after trauma or tumor excision with Integra and delayed grafting can often prevent the need for flap surgery or even, in the case of squamous cell carcinomas of the fingers, amputation.¹⁸ The development of new tissue-engineered adjuncts to wound healing remains a very active area of research in plastic surgery.

Negative-pressure wound therapy has become widespread and has been demonstrated to be efficacious and cost effective when applied appropriately for complex wounds.^{19,20} The commercially available VAC system (KCI, San Antonio, Texas) employs an open cell sponge that is applied to the wound and then sealed with an impermeable plastic dressing; negative pressure is applied to the sponge via tubing and pump. Extensive experimental and clinical data confirm that the VAC system promotes tissue perfusion, reduces edema, favorably alters wound fluid composition, and stimulates the formation of granulation tissue.¹⁹ The VAC system is easy to use; its primary limitation is related to cost. Additional cost-utility studies to justify its higher daily cost compared with simple dressings are required.

Multiple other modalities, such as hyperbaric oxygen treatment, are in use and are being developed on an ongoing basis, underscoring the high prevalence, the significant cost, and the clinical challenge that are posed by complex wounds. Despite

these ongoing developments, the basic algorithm for evaluation and nonsurgical management of wounds will not change.

Surgical Therapy

Wound Preparation. For problem wounds, surgical therapy is primarily aimed at wound preparation and wound reconstruction. For dirty wounds with necrotic debris, a judicious but thorough surgical débridement can convert a contaminated, chronic wound into a fresh surgical wound ready for immediate closure. Although débriding dressings can prepare wounds for closure under some circumstances, an operative débridement is preferred to a long course of débriding dressings for most problem wounds. Consequently, most complex wounds require an operative débridement prior to definitive reconstruction. In the case of chronic osteomyelitis, a formal resection of the sequestrum is required before formal wound closure. Prolonged treatment with intravenous or oral antibiotics cannot clear bacteria from a focus of dead bone; chronic osteomyelitis is a surgical disease cured with a saw, rongeur, bur, or bone curette. Therefore, the common practice of placing patients with chronic osteomyelitis on 6 weeks of antibiotic therapy is irrational unless performed in conjunction with a formal sequestrectomy.

Reconstructive Principles. As stated earlier, there is no “right” way to close any given wound. Plastic surgeons use a straightforward set of principles in delineating the optimum way to close a given wound for a given patient. The predominant principle is that the simplest method to close a wound is usually the best choice. This principle is embodied in the “reconstructive ladder,” which is a hierarchy of reconstructive options progressing from simple to complex (Table 113.3). Therefore, when engaging options for wound closure, plastic surgeons “climb” the reconstructive ladder, usually stopping on the lowest rung that will achieve a closed wound. However, other principles of reconstruction sometimes override a slavish adherence to the reconstructive ladder. The choice of a technique for wound closure should take into consideration the need for subsequent procedures and other factors that might mitigate skipping over simpler options for wound closure. An example would be an avulsion injury to the palm of the hand. Although it might be possible to close this wound with a skin graft, the need to restore flexor tendon function is preeminent in the hand, so that the use of a distant flap to provide a suitable bed for tendon grafting may be the preferred choice. In addition to the reconstructive ladder, other examples of guiding reconstructive principles are as follows: function takes precedence over form, single-stage reconstructions are preferred over multistage approaches, and autologous tissue is preferred over alloplastic reconstructions. Other factors to be considered are the durability of the reconstruction over many years, the psychological impact on the patient, and data indicating that some options are sometimes preferred for specific reasons. For example, muscle flaps are known to be superior to skin flaps in their ability to resist or eradicate infection.²¹ Therefore, a muscle flap may be chosen over a simpler option if the eradication of osteomyelitis or mediastinitis is the goal.

TABLE 113.3

ETIOLOGY

THE RECONSTRUCTIVE LADDER

1. Primary wound closure
2. Healing by secondary intention
3. Skin grafting
4. Local flaps
5. Regional flaps
6. Distant flaps

As mentioned earlier, weighing this complex array of factors to arrive at the optimal reconstruction for a given patient is the true challenge in reconstructive surgery.

Reconstructive Techniques. Regardless of the reconstructive method chosen, plastic surgeons strive for technical virtuosity in the operating room. To maximize healing and minimize scar formation, atraumatic technique includes delicate tissue handling, the use of skin hooks and sharp rakes, bipolar electrocautery, sharp dissection, and loupe magnification. When reconstructing difficult wounds, the margin for error is minimal, and small errors in technical execution can result in failure. The general surgical methods used by reconstructive surgeons are briefly considered in this chapter.

Primary Closure. If a laceration or other wound can be closed primarily, consideration is given to a meticulous, layered closure. Emphasis is placed on eversion of skin edges without strangling tissue. Nonabsorbable skin stitches that provoke minimal inflammatory response are preferred, but they must be removed promptly to minimize cross-hatching. Therefore, for most wounds, deep dermal, absorbable stitches are placed to allow early removal of skin stitches while still providing prolonged support to the repair; this may minimize the chances of a dehiscence or scar spread. It is preferable to place a closed-suction drain to eliminate dead space rather than suturing fat or other easily devascularized tissue. If a technically perfect, tension-free repair cannot be achieved with primary closure, it is preferable to use a more complex surgical option.

- 3 **Skin Grafting.** Skin grafting was one of the foundations on which the specialty of plastic surgery was established. Skin grafts are classified as either split thickness, where the epidermis and a portion of the dermis are harvested, or full thickness, where the epidermis and the entire dermis are harvested. Both full-thickness and split-thickness skin grafts can be used to resurface open wounds in cases in which primary closure is not possible. Skin graft take is contingent on the successful revascularization of the graft within a narrow time window (48 to 72 hours). Initially, grafts are nourished by a process of plasmatic imbibition, wherein serum from the wound bed diffuses into the adjacent graft. Revascularization occurs by the process of inosculation. Vessels from the wound bed grow into the graft, forming functional circulatory connections with the vasculature of the graft. For plasmatic imbibition and inosculation to be successful, two criteria must be met. First, the wound bed must be appropriately vascularized. Therefore, skin grafts cannot be placed on poorly vascularized wound surfaces, including bone denuded of periosteum, tendon denuded of peritenon, or cartilage. Second, a bolster dressing or splint must be used to ensure absolute immobilization of the graft on the bed to prevent shearing of the nascent vascular connections during inosculation. If either of these criteria cannot be met, a more complex reconstructive option must be considered.

Random Skin Flaps. The use of tissue (usually skin) immediately adjacent to the defect as the tissue for reconstruction is referred to as a local flap reconstruction. Skin rearrangement can range in complexity from simple undermining to complex, geometric skin flaps. Which method is appropriate is dependent on multiple factors, including the etiology of the defect, the desired direction of the scar, the fragility or mobility of underlying structures, and the need to avoid distortion to adjacent free margins such as the lip or eyelid. Significant experience is required for the optimal utilization of skin rearrangement. When plastic surgeons think of “classical” skin flaps, they are referring to random skin flaps, without an axial blood supply. These skin flaps rely on a dermal plexus of vessels for their survival, and the perfusion of the distal end of the flap is inadequate to allow tissue survival if the flap design is inap-

propriate. It was previously thought that survival of the distal part of random skin flaps could be ensured by adhering to length-to-width ratios established for various areas of the body. It is now recognized that these ratios have no basis in circulatory physiology, and the surviving length of a random skin flap does not depend on flap width.²² In practice, most of the commonly employed skin flaps have been developed empirically. There are three basic types of random skin flaps: rotation, advancement, and transposition, depending on how adjacent skin is shifted into the defect. Each type of flap has specific design criteria. Many eponyms are used to describe variations on these basic three flap designs; examples are the Romberg transposition flap, the Mustarde rotation flap, and the Rintala advancement flap. Excellent reviews of the use of skin flaps in reconstructive surgery are available.^{23,24}

As mentioned earlier, the concern with flap viability limits the utility of random skin flaps. Several strategies have been developed to circumvent this problem. The first of these is the concept of surgical delay. Delay is defined as the partial interruption of blood flow to a defined piece of tissue. At present, surgical delay is the only method available to augment the surviving length of random skin flaps (Fig. 113.1). Another strategy is the use of tissue expanders. Tissue expanders are implantable balloons that are inserted in a deflated state and are inflated with sterile saline via percutaneous injection into a self-sealing valve. Except for the scalp, where expanders are placed in the subgaleal plane, tissue expanders are usually placed subcutaneously. In fact, the insertion of the tissue expander into a subcutaneous pocket effects a surgical delay, and the slow expansion has been demonstrated to result in the formation of new skin. However, the most important strategy to circumvent the use of random skin flaps has been to develop axial pattern flaps that do not rely on a random blood supply.

Flaps with Axial Blood Supply. Regional flaps are defined as the transfer of tissue that is not immediately adjacent to the defect without the disruption of blood supply to the transferred tissue. For this approach to be practical, an axial blood supply to the transferred tissue must be present.

Axial Skin Flaps. The pioneering work of Bakamjian²⁵ and McGregor and Jackson²⁶ identified longitudinal blood vessels of large caliber traversing a defined region of skin. Their descriptions of the deltopectoral and groin flaps, respectively, opened a new era of reconstructive surgery. Surgeons were no longer constrained to the use of random skin flaps; any piece of tissue in the body with an axial blood supply could be transposed on a vascular pedicle with a high degree of assurance that the tissue would survive. Taylor and Palmer's²⁷ description of the angiosome concept solidified our ability to design flaps based on a sound knowledge of vascular anatomy. An angiosome is defined as a region of tissue supplied by an identifiable, and usually named, artery and its venae comitantes. Because of the ability of choke vessels crossing angiosome boundaries to enlarge, flaps can be designed to encompass an adjacent angiosome. However, flaps crossing two angiosome boundaries are destined to undergo partial necrosis. In practice, there are relatively few axial skin flaps, most being better classified as fasciocutaneous flaps.

Fasciocutaneous Flaps. Cormack and Lamberty²⁸ further expanded our understanding of the blood supply to the skin with their description of fasciocutaneous flaps. They pointed out that the dermal plexus derives its inflow from vertically oriented vessels arising at the level of the deep fascia. The vessels at the deep facial level have horizontal orientation relative to the skin's surface and form a subfacial plexus. This subfacial plexus can form the basis for the design of fasciocutaneous flaps based on several defined anatomic patterns.²⁸ Several fasciocutaneous flaps have enjoyed widespread use. The radial forearm flap has become a workhorse for hand reconstruction and as a free flap

FIGURE 113.1. Example of surgical delay. Because of associated medical problems, the patient was not a candidate for microvascular tissue transfer. **A:** Lower-third tibial defect secondary to an open ankle fracture. Note exposed bone, which precludes use of a skin graft. **B:** In the first stage, a bipedicle flap was created anterior to the defect. The deep perforators to the skin of the flap were divided by full undermining. The flap is perfused only from the proximal and distal ends. **C:** The incisions were repaired, and the wound was dressed. **D:** After 5 days, the bipedicle flap was again elevated and part of the distal pedicle was divided (arrow). The incisions were again closed, and the wound was dressed. This procedure was repeated 10 days after the initial operation to leave only a small skin bridge at the distal end of the flap. **E:** Fourteen days after the initial procedure, the remaining distal skin bridge was divided and the flap transferred. The donor site was skin grafted. This photograph depicts full survival of the flap and complete take of the skin graft.

for head and neck reconstruction. The osteoseptocutaneous fibula free flap has been widely used for intraoral reconstruction during reconstruction of oromandibular defects.

Muscle and Myocutaneous Flaps. Based on the knowledge that tissue with an axial blood supply can be reliably transferred, muscle and myocutaneous flaps came into widespread use in the 1980s, thanks in large part to the classification system by Mathes and Nahai.²⁹ Whole muscles can be transferred as a pedicled or free flap if a dominant vascular pedicle is present. Segmental muscle transfers are sometimes possible on minor vascular pedicles. Muscle flaps have enjoyed wide use for a diverse array of indications. As mentioned earlier, muscle flaps have an enhanced ability to eradicate infection and are pre-

ferred for contaminated or osteomyelitic wounds. For a given defect, muscle flaps are chosen by their size and arc of rotation.

4 The rediscovery of the musculocutaneous perforator as a predominant vascular supply to the skin in many areas of the body has led to the wide use of musculocutaneous flaps. These flaps derive their inflow from a major muscular artery. Perforators emanating vertically from the muscle surface supply the skin overlying the muscle. Table 113.4 lists “workhorse” muscle and myocutaneous flaps. Of particular note is the transverse rectus abdominis myocutaneous (TRAM) flap, based on periumbilical myocutaneous perforators from the rectus abdominis muscle, which has been widely employed for breast reconstruction.³⁰ An extension of this concept has led to the increasing use of “perforator” flaps. Perforator flaps are based

TABLE 113.4

CLASSIFICATION

WORKHORSE MUSCLE, MYOCUTANEOUS, AND PERFORATOR FLAPS

■ FLAP	■ MYOCUTANEOUS	■ PERFORATOR	■ COMMON USES
Temporalis	No	No	Orbital and intraoral reconstruction, facial reanimation (pedicled flap)
Pectoralis major	Yes	No	Intraoral and neck reconstruction; reconstruction of sternal defects (muscle only)
Latissimus dorsi	Yes	Yes	Breast reconstruction, neck reconstruction, free flap for very large defects
Rectus abdominis	Yes, including TRAM	Yes, including DIEP	Breast reconstruction, sternal reconstruction, reconstruction of groin defects, free flap for medium-sized defects
Gluteus maximus	Yes	Yes, including SGAP	Ischial pressure sores, sacral pressure sores, SGAP used for breast reconstruction
Biceps femoris	Yes	No	Ischial pressure sores
Tensor fascia lata	Yes	No	Trochanteric pressure sores, abdominal wall reconstruction
Gracilis	Yes	Yes	Perineal reconstruction, vaginal reconstruction, facial reanimation (muscle free flap), free flap for small defects
Rectus femoris	Yes	No	Infected hip wounds, abdominal wall reconstruction
Medial gastrocnemius	Rarely	No	Knee defects, proximal third tibial defects
Soleus	No	No	Middle third tibial defects

DIEP, deep inferior epigastric perforator; SGAP, superior gluteal artery perforator; TRAM, transverse rectus abdominis myocutaneous.

on fasciocutaneous or myocutaneous perforating vessels. Dissection isolates the skin and subcutaneous tissue to be transferred on one or more perforating vessels; the underlying muscle is left intact, eliminating the functional disturbance that would result if a whole muscle was harvested. Because of their robust vascularity and ability to minimize donor deficit, perforator flaps are a “growth area” in reconstructive surgery, and a large number of perforator flaps have now been described and are used as both pedicled and free flaps.³¹

Microvascular Tissue Transfer. Historically, pedicled flaps were used to reconstruct distant defects. The distant transfer was accomplished in one of two ways. Flaps could be moved to the defect in a series of pedicled transfers (waltzing or tumbling flaps). Alternatively, flaps could be attached directly to the defect with a temporary pedicle to the donor site being maintained temporarily. At a second stage the flap was detached from the donor site, after it had developed sufficient blood supply from the recipient bed (e.g., cross-leg flaps, pedicled groin flaps). Although the distant transfer of pedicled flaps still has definitive indications (e.g., the median forehead flap for nasal reconstruction), reconstruction using distant tissue is now most commonly performed via microvascular tissue transfer, or “free” flaps. First described clinically by Daniel and Taylor,³² free flaps have revolutionized reconstructive surgery. Any tissue with an axial blood supply with pedicle vessels 1 mm in diameter or larger can be reliably transferred microsurgically. Circulation in the transferred tissue is established via microvascular anastomoses between the axial flap vessels and vessels in the recipient site. Microvascular anastomoses are performed with 9–0 or 10–0 suture with the aid of an operating microscope; success rates for free-flap transfers exceed 90%.³³ The greatest advantage of free-flap reconstruction is that the surgeon is not restricted to the use of available, local tissues; any flap or composite block of tissue that has feeding vessels large enough for microvascular anastomoses (1 mm

diameter or larger) can be transferred with this technique. By using composite tissue flaps, massive, complex tissue defects can be reconstructed replacing “like with like”³⁴ (Fig. 113.2). Bowel, skin, bone, muscle, fascia, and composite tissue can be transferred microsurgically. Free flaps are the primary modality for reconstruction of major head and neck defects after composite resection of squamous cell carcinoma and for the reconstruction of traumatic defects in the distal foreleg. As already mentioned, perforator flaps are increasingly used as microsurgical tissue transfers. The anterior lateral thigh (ALT) perforator flap has become a workhorse for reconstruction for a diverse array of complex defects, especially after extirpative surgery of the head and neck,³⁵ and the deep inferior epigastric artery perforator (DIEP) flap now rivals the TRAM as the workhorse for autologous breast reconstruction.³⁶

RECONSTRUCTIVE AND AESTHETIC SURGERY OF THE BREAST

Plastic surgery of the female breast includes both reconstructive and aesthetic procedures. Breast reconstruction following mastectomy and reduction mammoplasty for macromastia (oversized breasts) are the most common examples of reconstructive breast surgery. By contrast, breast augmentation (enlargement) and mastopexy (breast lift) generally are performed for aesthetic reasons. Although some surgical approaches may be applicable to both categories of breast procedures, the relative benefits, risks, and costs of reconstructive versus aesthetic breast surgery may be quite different, particularly as viewed by patients, providers, and payers.

Before advising women on reconstructive or aesthetic breast procedures, the surgeon should carefully assess the patient's

FIGURE 113.2. Double free-flap reconstruction of a massive, complex defect. **A:** Squamous cell carcinoma of lip, chin, mandible, and floor of mouth after resection. Massive tissue defect encompasses skin of the chin, entire lower lip, mandible from midbody to midbody, and floor of the mouth. **B:** Fibula free flap. Skin paddle is centered on fasciocutaneous perforators. **C:** Fibula free flap elevated but still in situ. Osteotomies have been performed to conform to the mandibular contour. The skin paddle will form the floor of the mouth. **D:** Radial forearm free-flap plan. Skin paddle will be harvested along with the palmaris longus tendon. The tendon will be attached to the modiolus on either side of the lower-lip defect, and the skin paddle will reconstruct the skin of the chin and lip. For the lip, the skin paddle will be draped over the tendon like a bed sheet on a clothesline. **E:** Radial forearm flap elevated but in situ. **F:** Postoperative result, mouth closed. **G:** Postoperative result, mouth open. Double free-flap reconstruction of massive defects involving the lip, chin, and mandible. *Microsurgery* 1998;18:372–378.)

current preferences, concerns, history, and physical findings. Initially, any history of breast disease (as well as familial history of breast pathologies) should be evaluated. On physical examination, careful linear measurements and preoperative photographs should be taken to document existing contour deformities, asymmetries, or other findings. A standard breast examination should be carried out to detect previously undiagnosed masses, nipple discharge, or lymphadenopathy. Finally, it is also advisable that women age 40 years or older undergo mammography unless this study has been performed in the previous 12 months.

Preoperative consultation should include a thorough discussion covering the relative benefits and risks of the various surgical options. The surgeon is well advised to provide comprehensive information in an understandable format. To enhance patient satisfaction with the eventual surgical result, providers should elicit patients' preferences and expectations for surgical outcomes and tailor treatment options accordingly. Because of the prevalence of breast cancer in North American women, the impact of reconstructive or aesthetic procedures on breast cancer monitoring also should be discussed.

Reconstructive Breast Surgery

- 5 Postmastectomy Reconstruction.** A variety of operative procedures have been described for breast reconstruction following mastectomy. These approaches can be categorized as implant-based, autogenous (natural) tissue, and "hybrid" procedures. For purposes of this discussion, the term *hybrid* is applied to procedures combining elements of both implant and autogenous tissue techniques. This overview describes the advantages and disadvantages of the most common techniques. Ultimately, procedure selection is based on a range of patient variables, including size and shape of the desired reconstructed breast; availability of local, regional, and distant donor tissues; coexisting medical problems; and, perhaps most important, patient preferences.

Implant-based Techniques. As most commonly practiced, the implant approach usually requires two operative procedures to reconstruct the female breast. In the first stage, a temporary tissue expander is placed in a soft tissue pocket, usually located deep to the pectoralis major muscle. The tissue expander is a deflated Silastic (silicone) envelope with an integrated or remote injection port through which saline solution can be percutaneously injected. Following expander placement and meticulous closure of the overlying muscle and skin, saline is periodically injected beginning at 10 to 21 days (Fig. 113.3A). As the device enlarges, growth is induced in the overlying skin, recreating soft tissue coverage for the new breast.³⁷

Following completion of expansion, most surgeons delay the second stage of reconstruction for 1 to 4 months to allow for maximal skin growth. At the conclusion of this hiatus, the second procedure is performed, consisting of removal of the expander and placement of the reconstructive implant (Fig. 113.3B). Currently available breast implants include a range of options, including variations in shape (round vs. "anatomic" or teardrop configurations), fill material (silicone gel vs. saline), and surface configuration (smooth vs. textured envelopes). The relative advantages and disadvantages of these options are discussed in the Breast Augmentation section later in this chapter. As the most common option for postmastectomy reconstruction in the United States, the expander-implant approach offers several advantages. The surgical procedures associated with this approach usually are relatively brief (often 1 hour or less) and are technically straightforward. Particularly when employed in concert with procedures on the contralateral breast (i.e., breast reduction, mastopexy, or augmentation), resulting symmetry and aesthetic outcomes are relatively good.

Patients considering implant reconstruction should also be mindful of the disadvantages of these procedures. The expander-implant approach usually requires two surgical procedures, multiple visits for expansion, and approximately 4 to 6 months to complete. For patients eager to return to a normal lifestyle following breast cancer treatment, this delay can be particularly frustrating. In addition, tissue expanders and

FIGURE 113.3. Expander-implant reconstruction.

reconstructive implants have been associated with a number of complications. Early in the postoperative period, these devices may be troubled by delays in wound healing, at times resulting in implant exposure and requiring explantation. Implant infections also may necessitate removal of the prosthetic device. Late complications include expander or implant leakage. Also, the development of excessive scar tissue surrounding the implant (termed a *capsular contracture*) can produce a hard, painful, or deformed breast requiring surgical revision.

6 Autogenous Tissue Reconstruction. A variety of autogenous (natural) tissue options have been described for postmastectomy breast reconstruction. Currently, the most commonly performed of these procedures is the TRAM flap. Originally popularized by Hartrampf et al.,³⁰ the TRAM flap is most commonly performed as a pedicle muscle flap; that is, the transferred rectus muscle is left partially attached to the costal margin, preserving the superior epigastric artery and vein as the flap's blood supply (Fig. 113.4A, B). In pedicle TRAM reconstruction, the rectus muscle serves as the vascular carrier for a large ellipse of lower abdominal skin and fat. These tissues are tunneled subcutaneously into the mastectomy defect, where they are sculpted into the desired breast size and shape. Meanwhile, the abdominal donor site is closed by reapproximating the anterior rectus sheath and by advancing the remaining superior skin edge of the donor site as a modified abdominoplasty (Fig. 113.4C).

Pedicle TRAM reconstruction offers several benefits. Because the TRAM flap usually provides a generous amount of

lower abdominal adipose tissue for breast bulk, implants are rarely needed with this approach. The TRAM flap can be inset and sculpted in a virtually infinite number of ways, giving the reconstructive surgeon considerable latitude in the creation of breast shapes and sizes. Furthermore, in contrast to implant approaches, TRAM reconstruction is a one-stage technique, requiring only a single surgery to recreate the breast mound. An additional advantage of TRAM flaps is their tendency to gain or lose volume in association with weight changes and body mass, thereby maintaining better symmetry than implant reconstructions over time. Among reconstructive surgeons, there appears to be a growing consensus that TRAM flaps produce superior aesthetic results compared with other techniques.

Despite these advantages, TRAM flaps also are associated with several disadvantages. Compared with implant approaches, TRAM reconstruction requires longer operations, hospitalizations, and recovery times. Furthermore, TRAM procedures can produce a range of complications, including partial and total flap loss as a result of vascular compromise of the transferred tissue. Also, occurrences of postoperative abdominal hernias or (more commonly) abdominal wall laxity remain persistent issues for some patients choosing TRAM reconstruction.³⁸

Although the pedicle TRAM flap is the most frequently employed option for autogenous tissue breast reconstruction, free tissue transfer has received growing attention as a potentially useful technique for recreating the breast mound. In particular, the free TRAM flap has been promoted by Kroll and Baldwin,³⁹ Grotting et al.,⁴⁰ and Allen and Treece⁴¹ as

FIGURE 113.4. Transverse rectus abdominis myocutaneous (TRAM) flap reconstruction.

FIGURE 113.5. Free transverse rectus abdominis myocutaneous (TRAM) flap reconstruction.

producing superior results compared with the pedicle version of the flap. With the free TRAM flap, a lower abdominal segment of skin and fat is harvested based on the deep inferior epigastric artery and vein. A small island of rectus abdominis muscle also is included with the flap, mainly to facilitate inclusion of small perforating vessels that travel from the deep inferior epigastric artery and vein into the overlying skin and fat (Fig. 113.5). Using microsurgical techniques, the flap's vascular pedicle is then anastomosed to recipient vessels (usually the thoracodorsal, subscapular, or internal mammary vessels) adjacent to the mastectomy site. In the views of Grotting et al.⁴⁰ and other investigators,²⁹ free TRAM flaps offer the potential advantages of greater flap reliability, superior aesthetics, and preservation of abdominal wall integrity.

Allen and Treece⁴¹ and Allen and Tucker⁴² have taken the free TRAM flap a step further with their development of the deep inferior epigastric perforator flap: by meticulously dissecting vascular perforators from the deep inferior epigastric pedicle into the overlying abdominal fat, these investigators have been able to avoid removal of any rectus abdominis muscle with free TRAM harvest, thereby minimizing disruption of abdominal wall structures.⁴¹ The free perforator flap concept also has been applied to other donor sites for breast reconstruction, most notably the superior gluteal artery perforator flap.^{42,43} Although they appear to avoid the functional deficits associated with muscle flap harvest, perforator flaps (like all free tissue transfers) entail long, technically difficult operations requiring special facilities, equipment, and expertise. Also, because the blood supply for the entire flap depends on two or three microsurgical anastomoses (each usually involving vessels no more than 2 to 3 mm in diameter), there is the potential for complete flap loss in the event of anastomotic thrombosis.

“Hybrid” Breast Reconstruction Techniques. As an additional alternative for breast reconstruction, flaps can be used in concert with saline or silicone gel implants. Most commonly, the ipsilateral latissimus dorsi and a segment of overlying skin are harvested as a musculocutaneous pedicle flap and are tunneled anteriorly into the mastectomy defect (Fig. 113.6A–C). Although the latissimus dorsi and its associated skin island constitute an extremely reliable flap when used for wound coverage, this approach usually provides insufficient

FIGURE 113.6. Latissimus dorsi flap reconstruction.

bulk for breast volume. Tissue expanders or implants are often used to address this volume deficiency. The combination of a latissimus dorsi flap and tissue expansion may be particularly appropriate for cases in which the remaining mastectomy skin is of insufficient quality or quantity to tolerate tissue expansion. Following transfer and expansion of a latissimus dorsi musculocutaneous flap, an appropriately sized breast implant usually can be safely placed in a secondary operation.

From 1994 to 2000, the Michigan Breast Reconstruction Outcome Study evaluated long-term results in women undergoing expander–implant, pedicle TRAM, and free TRAM procedures in 12 centers across the United States. A variety of outcomes were assessed, including complications. Table 113.5 summarizes the complications by procedure type.⁴⁴

Nipple–Areolar Reconstruction. Reconstruction of the nipple–areolar complex (NAC) can be accomplished at the conclusion of breast mound reconstruction or at a later date. Following recreation of the mound, many surgeons prefer to allow several months for tissue healing and settling before proceeding with nipple–areolar reconstruction. To recreate the papule, common options usually rely on local skin flaps or a segment of redundant contralateral papule. For the areola, a full-thickness skin graft or tattooing of the surrounding skin can be used.

Breast Reduction (Reduction Mammoplasty). Because reduction mammoplasty is intended to alleviate functional problems and symptoms of macromastia, this procedure is considered a reconstructive rather than an aesthetic operation. In general, appropriate candidates for reduction mammoplasty are women with macromastia and associated back, neck, or shoulder pain; limitations in daily work or recreational activities; or difficulties obtaining proper fit in bras or other clothing. Although reduction mammoplasty usually is a covered benefit by most health care payers, patients' symptomatic and functional concerns must be carefully assessed and documented before proceeding with surgery. As noted earlier in this section, patients' preferences and expectations regarding postoperative breast size, shape, and functional results should also be carefully evaluated.

TABLE 113.5

CLASSIFICATION

MICHIGAN BREAST RECONSTRUCTION STUDY FREQUENCY OF COMPLICATIONS BY TYPE OF RECONSTRUCTION

■ COMPLICATION	■ TOTAL PATIENTS: 325					
	■ IMPLANTS (n = 79)		■ PEDICLE TRAM FLAPS (n = 179)		■ FREE TRAM FLAPS (n = 67)

TRAM, transverse rectus abdominis myocutaneous.

Although a variety of approaches have been described for breast reduction, common surgical options share a number of characteristics. Most techniques of breast reduction resect both breast parenchyma and redundant skin. Also, reduction procedures generally reposition the NAC to a more superior point on the breast mound. To maintain nipple viability and sensation, the NAC usually is mobilized as part of a pedicle of breast parenchyma or dermis. Following dissection of the nipple pedicle and reduction of the surrounding breast skin and parenchyma, the pedicle is transferred superiorly with its vascular and neural supplies intact, while the remaining breast is reapproximated around the nipple pedicle.

In categorizing reduction mammoplasty techniques, surgical options often are described in terms of the nipple pedicle design. For example, the most common approaches rely on an

inferiorly or centrally based dermal-parenchymal pedicle to maintain vascular and nerve supplies to the NAC (Figs. 113.7A–C and 113.8A–C).^{45–47} In designing skin incisions, traditional methods of reduction often have incorporated a modification of a pattern originally described by Wise.⁴⁸ While allowing considerable flexibility in resection of redundant breast skin, the modified Wise pattern produces an inverted T-shaped scar, the inferior portion of which runs along the infra-mammary fold (IMF). In an effort to eliminate the IMF scar, Lejour⁴⁹ and Hammond⁵⁰ have described a vertical scar reduction mammoplasty.

Prospective outcome analysis of women undergoing reduction mammoplasty indicate that this surgical intervention produces considerable improvements in somatic pain and in functional status.^{51,52} However, patients and providers also should

FIGURE 113.7. Inferior pedicle technique for reduction mammoplasty.

FIGURE 113.8. Central pedicle technique for reduction mammoplasty.

be aware of the potential risks associated with reduction. Complications reported with these procedures include instances of nipple or skin loss, changes in levels of nipple sensation, hypertrophic scarring or keloid formation, contour deformities, and breast asymmetry.

Aesthetic Breast Surgery

Breast Augmentation (Augmentation Mammoplasty).

Augmentation or breast enlargement is one of the most commonly performed aesthetic procedures. Evaluation of patients seeking breast augmentation should follow the guidelines described earlier. Particular attention should be focused on thoroughly assessing several factors, including patient preferences for postoperative breast size and shape, history of breast disease, and physical findings. The preoperative examination should evaluate and document any possible breast masses as well as existing breast size, asymmetries, and contour deficits.

In planning augmentation mammoplasty, a variety of approaches and options are available. Decisions regarding these choices are best reached in consultation with the patient. Implants can be placed through a variety of incisions including periareolar, inframammary fold, and transaxillary approaches. With the advent of endoscopic techniques in recent years, transaxillary augmentation now can be carried out with direct visualization of the implant pocket. This latter approach commonly produces excellent aesthetic results with minimal visible skin scarring.

Location of the implant pocket is another critical decision in augmentation mammoplasty. Implants can be placed anterior to the pectoralis major muscle ("subglandular" location) or posterior to the muscle ("subpectoral" location). Subglandular placement usually results in less postoperative pain, but a submuscular implant location may produce lower rates of capsular contracture⁵³ and may pose fewer difficulties in obtaining subsequent mammograms.⁵⁴

Several choices also exist in selection of implant types. Since the mid-1990s, many surgeons have relied on the use of

implants with textured surfaces to reduce capsular contracture rates. Although textured surfaces appear to lessen scar tissue contracture,⁵⁵ some patients and surgeons assert that, compared with the smooth-walled envelope, the thicker, less pliable textured envelope gives the augmented breast a less natural appearance and feel. With the recent reintroduction of silicone gel-filled implants under research protocols in selected centers, patients and providers also have a choice of implant fill materials. Although gel implants may produce aesthetically superior results compared with saline implants in some patients, diagnosis and surgical treatment of implant rupture may be more challenging with gel devices.

Whatever options are chosen for breast augmentation, surgeons should clearly communicate with patients about the potential risks of these procedures. The most commonly reported complications include implant rupture, capsular contracture, implant infection, contour deformities, and breast asymmetries.⁵⁶ Despite the potential for local complications, there currently is no substantial evidence that silicone gel filler material or implant envelopes are associated with increased risk for systemic disease. At this writing, concerns voiced in the early 1990s about adverse "health effects" of silicone breast implants appear to be unfounded.⁵⁷

Mastopexy. Mastopexy (or "breast lift") describes a category of surgical procedures designed to address redundancy or laxity of the breast's skin envelope, a condition termed *ptosis of the breast*. Breast ptosis can be classified as mild, moderate, or severe, depending on the location of the NAC relative to the inframammary fold (Fig. 113.9). Ptosis occurs when an imbalance exists between the volume of breast parenchyma and the quantity of overlying skin. Mastopexy procedures usually reduce ptosis by removing redundant breast skin and by relocating the NAC to a more superior position. These goals can be achieved through a variety of skin incisions and excisions, many of which closely resemble techniques described earlier for reduction mammoplasty. Fundamentally, mastopexy differs from breast reduction in that mastopexy removes redundant skin while leaving most or all of the breast

FIGURE 113.9. A: Mild ptosis. B: Moderate ptosis. C: Severe ptosis.

parenchyma. Approaches to mastopexy range from minimal periareolar techniques to more extensive skin resections using more extensive vertical incisions (Fig. 113.10A, B). As always, patients considering this procedure must weigh the potential benefits of mastopexy (most notably, diminished ptosis) with the disadvantages (scars and risks of complications) associated with the operation. Although relatively rare, the potential complications of mastopexy closely parallel those described for reduction mammoplasty.

RECONSTRUCTIVE SURGERY OF THE HAND

Advances in plastic surgery have improved our ability to reconstruct hands that have been mutilated by trauma, destroyed by arthritic diseases, or impaired by congenital conditions. Innovations in microvascular techniques, wound management, and rigid fracture fixation have expanded the capabilities of plastic

surgeons by allowing them to borrow tissues from other parts of the body and use them to reconstruct complex defects in the upper extremity in a single procedure. These innovations provide limitless technical possibilities for the restoration of hand function and the eventual return of patients as productive members of society. The following sections highlight the technical aspects of hand reconstruction and discuss indications for and applications of these techniques.

Trauma

Replantation. Since the first successful finger replantation by Komatsu and Tamai⁵⁸ in 1968, replantation surgery has flourished throughout the world. Thirty years of experience with replantation surgery has improved our understanding of this procedure and has resulted in the development of indication guidelines to ensure that replanted upper extremity parts not only survive but also have acceptable function. The absolute indications for replantation (i.e., situations in which replantation should always be attempted) are (a) thumb amputation, (b) multiple finger amputations, (c) pediatric population amputations, and (d) midhand, wrist, or distal forearm amputations. The absolute contraindications for replantation are (a) associated life-threatening injuries; (b) multiple-level injury in the amputated part, causing injuries along the vessels and preventing blood flow into the replanted part; and (c) severe contamination of the part, which carries a high probability of systemic infection if replanted. There are other situations in which the benefit of replantation is debatable because outcome data are not available. For example, single finger amputation at zone II (a tight fibro-osseous tunnel extending from the insertion of the superficialis tendon at the middle phalanx to the first annular pulley) is generally not recommended. Tendon adhesion after zone II replantation may result in a stiff finger, which can interfere with the overall performance of the hand. On the other hand, single-finger amputation at zone I (distal to the superficialis insertion) is often recommended (Fig. 113.11). A stiff distal interphalangeal joint generally does not cause much impairment, and nerve regeneration to the replanted part is quite rapid because of the short distance to the terminal sensory organs. Furthermore, the aesthetic appearance of zone I replantation is far superior to that of an amputation stump. In the future, the use of patient-related outcome instruments and an increased body of replantation experience among centers will help to define the utility of various digit replantation procedures.

FIGURE 113.10. Mastopexy procedures. (Redrawn from Bostwick J. *Plastic and Reconstructive Breast Surgery*. St. Louis, MO: Quality Medical Publishing; 1990.)

FIGURE 113.11. A: Amputation of the index finger at zone 1 in a mechanic. The patient requested replantation because his work requires fine manipulative tasks. B: Successful replantation with good aesthetic outcome and function.

Toe Transfer

When finger replantation is not possible or not successful, patients are left with significant functional loss. Disability is most severe when the thumb has been amputated at or proximal to the metacarpophalangeal joint or when all of the fingers have been amputated in machine injuries. In these cases, toe transfer to the hand is an effective procedure in restoring grasp and pinch function. Although a prosthesis is available to mimic the thumb, lack of sensation is a major drawback and often leads to disuse of the prosthesis. For a patient who has had a thumb amputation at or proximal to the metacarpophalangeal joint, big toe or second toe transfer to the thumb can create a sensate digit that will oppose to the other fingers. Big toe transfer is advantageous because it provides a broad contact surface and closely resembles the shape of the thumb, particularly when the big toe is trimmed and sculptured to match the size of the thumb. However, the disadvantage of the big toe transfer is the conspicuous donor site appearance in the foot and potential gait problems with foot push-off if the head of the first metatarsal is taken along with the big toe. For these reasons, the second toe has become the preferred method of transfer in some centers (Fig. 113.12). The disadvantage of the second toe transfer procedure is the slender appearance of the digit as compared to the original thumb, but the donor site appearance is quite acceptable. A recent outcome study, using objective physical measurements and validated outcome questionnaires, demonstrated that toe-to-thumb transfer is an effective procedure in restoring hand function.⁵⁹ In addition, patients did not complain of gait difficulty after either big toe or second toe transfer.

One of the most complex problems in hand surgery is the reconstruction of a hand without digits. To create a new hand capable of tripod pinch, plastic surgeons can transfer multiple toes from both feet to the hand (Fig. 113.13). This type of reconstruction can restore function to an otherwise useless

hand and has allowed two farmers who were treated at one center to return to heavy farm labor.

Complex Hand Injuries

Although crush injuries to the hand are common, injuries associated with sufficient force to disrupt the structural integrity of the wrist and to sever the blood supply to the hand are uncommon events (Fig. 113.14). Because multiple structures are traumatized in injuries of this kind, a systematic treatment approach is important in salvaging the hand and in restoring its function. Crucial steps in the management of this injury are (a) ruling out other injuries, (b) aggressive débridement, (c) skeletal fixation, (d) decompression of fascial compartments in the hand, (e) revascularization, (f) tendon repair, (g) nerve repair, and (h) early soft tissue coverage (within 1 week of injury) (Table 113.6).

Excluding Other Injuries. In devastating trauma, attention is often focused on the obvious injury, and injuries to other organ systems may be ignored. In a review of 1,100 patients referred for emergent microsurgery over a 7-year

TABLE 113.6 **COMPLICATIONS**

COMPLICATIONS OF TREATMENT OF COMPLEX HAND INJURIES

Inadequate débridement of contaminated tissue
Poor fixation technique for bone injuries
Postponement of soft tissue coverage, over 1 wk after injury
Free-flap pedicle anastomosis within the zone of injury
Delay in hand therapy

FIGURE 113.12. A: Second-toe transfer for thumb reconstruction in a carpenter. He sustained a thumb amputation at the metacarpophalangeal joint while using a saw at work. B: Good function with restoration of fine pinch. The patient returned to work as a carpenter 3 months after the toe reconstruction.

FIGURE 113.13. A: A farmer who lost all his fingers when he was injured by a corn picker. A groin skin flap was used to cover the exposed metacarpal heads. B: A second toe was removed from one foot to reconstruct the thumb, and the second and third toes were removed together from the other foot to reconstruct the fingers. Note the good opposition of the thumb and acceptable flexion of the digits. The patient returned to work on his dairy farm after the hand reconstruction.

FIGURE 113.14. A: Accidental shotgun blast injury in a 16-year-old boy. Both the radial and ulnar arteries were ruptured, and the hand was ischemic. The wrist was destroyed, and multiple tendons and nerves were severed. B: Volar wrist wound. Markings show incision lines for ulnar artery exposure.

period, investigators found nine cases (0.8%) of unrecognized life-threatening injuries that required abandonment of the microsurgical procedures.⁶⁰ Therefore, systematic trauma evaluation and ruling out other associated injuries should precede treatment of the hand injury.

Débridement. Severe crush and blast injuries are associated with large zones of injury, and the wounds may be contaminated with foreign materials such as grease or paint, as in printing-press injuries. In these cases, aggressive débridement is important in preventing infection. Except for critical structures that include nerves and tendons, all devitalized soft tissues and bone fragments must be excised. The concept of radical débridement has been shown to decrease wound infection and improve the success of microvascular reconstruction.⁶¹

Skeletal Fixation. After débridement, the next priority is to stabilize the wrist and to rigidly fix hand fractures. A stable wrist provides a platform for repairing other injured structures. If the crush injury is associated with comminuted fractures of multiple carpal bones and rupture of the intercarpal ligaments, wrist fusion may be the best option because it is often impossible to reconstitute the normal anatomy of the distal and proximal carpal rows in the face of severe comminution of the carpal bones. To avoid possible bone graft contamination with primary wrist fusion, external fixators are placed for provisional fixation during the initial débridement. Definitive wrist fusion with bone grafting is performed after adequate débridements and during the flap coverage procedure. Two 2.7-mm fixator pins are placed through an incision along the radial index metacarpal, and two proximal 3.5-mm pins are placed into the radius using an incision along the radial border of the distal radius, between the brachioradialis and the extensor carpi radialis longus. The superficial radial nerve, which lies under the brachioradialis, is dissected free and retracted away from the pins. External fixator rods are

then secured to the pins with nuts and screws. If the wound is clean during the second-look procedure at 24 or 48 hours, total wrist fusion is then undertaken (Fig. 113.15). Otherwise, the external fixator is left in place until the wound is suitable for fusion using internal plating and cancellous bone grafts. This stable skeletal fixation allows early hand therapy, usually instituted on postinjury day 7 when tissue edema is subsiding.

Revascularization. In a crush injury of the wrist, the zone of injury can be extensive. Use of vein grafts is essential in performing the arterial anastomosis away from the zone of injury. The ulnar artery is chosen for repair because it is the dominant artery in most patients and because it can be exposed readily in the hypothenar area. If the ulnar artery is contused in the palm, distal anastomosis can be performed to the superficial palmar arch. Because soft tissue bridges are often present, venous outflow is not a problem and venous anastomosis is not necessary.

Decompression of Fascial Compartments. Increased edema associated with crush injuries often raises the compartmental pressures in the intrinsic muscle compartments and in the carpal tunnel. Prior reviews have shown a high incidence of ischemia and resultant fibrosis of the intrinsic muscles following crushing trauma to the hand.⁶² Consequently, surgeons perform prophylactic carpal tunnel releases and intrinsic muscle decompressions in severe crush injuries of this kind.

Soft Tissue Coverage. After aggressive débridement, a soft tissue defect is often present around the wrist. A split-thickness autograft is placed over the vein graft to prevent desiccation. Other open wounds can be covered temporarily with homografts. If wrist fusion is undertaken during the second-look procedure, primary wound closure can be achieved. For residual wound defects, split-thickness autografts are used to cover the exposed muscle bellies. However, if tendons or nerves are

FIGURE 113.15. A, B: Note destruction of the wrist joint, in addition to comminuted fractures of the distal ulna and radius. C: Total wrist fusion was performed 48 hours after the initial injury.

exposed, coverage with either fasciocutaneous or muscle free flaps will allow earlier tendon mobilization and prevent tendon adhesions. Definitive early wound coverage is important in protecting vital structures and avoiding wound colonization with bacteria (Fig. 113.16).

Nerve Repair. When nerves are crushed, the delineation between viable and nonviable nerve fascicles is difficult to

assess in the acute setting. Therefore, the traditional approach is to delay the nerve grafting procedures until 2 or 3 months after injury. To prevent retraction of the nerve ends, we suture the nerve ends to the surrounding soft tissues. However, secondary nerve grafting is often difficult because of the amount of scar in the wound. One way to deal with this situation is to primarily graft the nerve injury at the expense of more aggressive resection of the traumatized nerve ends.

FIGURE 113.16. A: A free rectus abdominis muscle was used for immediate coverage of the reconstructed wrist and tendons. B: The hand was salvaged, and the patient has acceptable hand function after secondary nerve and tendon reconstruction.

- 8 In conclusion, rigid skeletal fixation, revascularization using vein grafts, and immediate wound coverage are crucial factors in successful limb salvage.

Congenital Anomalies

Syndactyly. Syndactyly is a condition in which the fingers are fused. Syndactyly can be classified as complete or incomplete. Complete syndactyly is the union of the digits extending to the distal phalanx. Incomplete syndactyly is the union of the digits proximal to the distal phalanx but distal to the normal webbing at the midproximal phalanx. Syndactyly is further categorized as simple or complex. In simple syndactyly, there is no bony union between the digits, whereas complex syndactyly includes bony union.

Typically, syndactyly can be separated when the child is 1 year of age. Surgery should be performed earlier if syndactyly affects the thumb–index finger or ring–little finger web space and causes deviation of the shorter digits during growth. Separating the fingers requires meticulous design of the skin flaps, and the dorsal skin flap is most crucial to creating a web space that is not prone to contracture (Fig. 113.17). Distally, triangular skin flaps are designed to drape the sides of the fingers. A full-thickness skin graft from the groin is often required to cover open areas in the fingers.

Thumb Duplication. Although thumb duplication does not often cause a functional problem for the child, the presence of this prominent hand malformation can have a significant impact on the child's psychosocial development. Surgery can be undertaken when the child is about 2 years old to prevent

FIGURE 113.17. A: A simple, complete syndactyly in a 1-year-old child. Note the design of the dorsal skin flap to reconstruct the web space and the interdigitating distal skin flaps. B: Immediate postoperative photograph of the syndactyly release.

FIGURE 113.18. A: Wassel type 3 thumb duplication in a 2-year-old child. B: The radial digit was hypoplastic and was removed. C: Intraoperative picture shows the aesthetically pleasing reconstructed thumb.

progressive deviation of the thumb during growth. Thumb duplication can be classified into seven groups, depending on the level of the duplication. Type I consists of a bifid distal phalanx, whereas type II is a complete duplication of the distal phalanx. Types III and IV involve the proximal phalanx, and types V and VI involve the metacarpal. Type VII is a triphalangeal thumb or a thumb with three phalanges. Usually the radial, less developed thumb is removed. Retention of the ulnar thumb has the added advantage of preserving the important stabilizing ulnar collateral ligament. The surgery requires a delicate reconstruction of the bone, ligament, and tendon structures to sculpture the remaining thumb as normally as possible (Fig. 113.18). After the immediate postsurgical period, these patients are followed once a year to evaluate potential growth abnormality.

Hypoplasia and Aplasia of the Thumb. The thumb contributes about 50% of hand function and is important in pinch and grip. Reconstruction of the underdeveloped thumb is critical in improving hand function for the child. Hypoplasia of the thumb can be classified into five grades, and treatment options are often based on this classification. Grade I consists of minor hypoplasia; all components of the thumb are present, but the thumb is smaller than normal. Grade II consists of adduction contracture of the first web space and laxity of the ulnar collateral ligament at the metacarpophalangeal joint; the thenar musculature is hypoplastic but the skeletal framework of the thumb is normal. Grade III includes severe hypoplasia of the thumb with absent intrinsic muscles

and underdeveloped extrinsic tendons; the skeletal framework is hypoplastic and the carpometacarpal joint is vestigial. Grade IV is characterized by a floating, nonfunctional thumb (pouce flottant), with soft tissue attachment of the thumb at the metacarpophalangeal joint of the index finger. Grade V is defined by total absence of the thumb. Grade I hypoplasia does not require treatment and grades III, IV, and V require index pollicization (reconstructing a thumb using the index finger) for optimal function (Fig. 113.19). In grade II, the thumb can be reconstructed by using a combination of tendon, joint, and soft tissue procedures.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a crippling disease that severely affects the quality of life for millions of Americans. RA is postulated to be an autoimmune disease mediated by inflammatory cells that attack the synovial tissues in the body. Persistent synovitis in the joints causes erosion of the articular surfaces and disrupts their soft tissue supports.

Because the hand is often damaged by RA, effective surgical treatment of hand deformities can improve patient function and restore independence. The goals of surgery for the rheumatoid hand include (a) pain control, (b) improvement or restoration of function, (c) prevention of disease progression, and (d) aesthetic improvement. To accomplish these goals, the surgeon must have good rapport with both the rheumatologist and the patient as priorities of treatment are determined. By

FIGURE 113.19. A: Absence of a thumb in a 2-year-old child. Note the floating thumb attached to the index finger. B: Immediate appearance in the operating room after pollicization. C: Three months after index pollicization, the child is able to use the new thumb for grasp and fine pinch.

listening to patients with RA describe their impairments and their goals, the surgeon can gain insight into the surgical plan that will offer the patient the most benefit.

Surgical treatment can be classified as preventive, corrective, or salvage.⁶³ Preventive procedures include tenosynovectomy to avoid tendon rupture and synovectomy to ameliorate ongoing joint destruction from erosive synovitis in the joints. Corrective procedures include tendon transfers for tendon ruptures and nerve decompression for carpal tunnel syndrome. Salvage procedures consist of joint arthroplasty and joint fusion.

A common hand deformity in RA consists of subluxation and ulnar deviation of the fingers at the level of the metacarpophalangeal joints (MPJs) (Fig. 113.20). Synovitis at the MPJs distends the joints and attenuates the supporting ligaments. Wrist destruction in RA contributes to the radial deviation of the metacarpals, which accentuates the ulnar deviation of the fingers. With progressive MPJ disease, patients have great difficulty opening their hands because of subluxation of the MPJs and difficulty with fine pinch because of the ulnar deviation of the fingers. In addition to pain at the MPJs secondary to their worn articular surfaces, RA patients often complain of the aesthetic appearance of their hands.

The Swanson metacarpophalangeal joint arthroplasty (SMPA) is an effective procedure that will meet all four goals of RA surgery. By replacing the arthritic joints with prosthetic spacers and realigning the soft tissue envelope around the MPJs, surgeons are able to markedly improve function and enhance the aesthetic appearance of RA hands. A recent systematic overview of the world's literature on this procedure showed that SMPA is an effective procedure in improving the health-related quality of life for RA patients.⁶⁴

AESTHETIC SURGERY

Plastic and reconstructive surgery is a discipline that adapts broad surgical principles to a multitude of unique clinical problems by altering form and function. Plastic surgery not only restores physical function but also enhances a patient's

FIGURE 113.20. Severe destruction of the metacarpophalangeal joints with ulnar deviation of the fingers of the left hand. Note restoration of normal finger alignment of the right hand after Swanson metacarpophalangeal joint arthroplasty.

body image and self-esteem. In no other area of surgery is this more true than in aesthetic surgery. A blepharoplasty may not only improve the appearance of baggy, tired eyes but also may treat visual field defects caused by eyelid ptosis or blepharochalasis. A rhinoplasty can improve the outward appearance of a nose as well as nasal airflow and breathing.

- 9 Aesthetic surgery requires meticulous attention to detail, careful patient selection, rigorous procedural planning, and precise execution of technically challenging procedures. If patients are carefully selected and their goals are realistic, then the chances for a successful outcome are good. However, if patients are poorly selected or they have unrealistic goals, then a technically successful operation with an aesthetically pleasing outcome may be a dismal failure in the eyes of the patient. The aesthetic surgeon must not only diagnose the clinical deformity but also carefully evaluate the patient's expectations and motivations for surgery. Through the application of sound surgical principles and technical expertise, the aesthetic surgeon can experience lifelong career and personal satisfaction.

Cosmetic Procedures for the Head and Neck

Brow Lift. Brow ptosis is a natural consequence of the biologic process of aging. If left uncorrected, patients can appear angry, tired, or older than their chronologic age. If severe, brow ptosis may cause visual field obstruction on upward gaze; correction of this deformity can produce dramatic functional and aesthetic improvements. Patients frequently present with the complaint of looking tired or angry and request a blepharoplasty. In many cases, the etiology of their complaint is brow ptosis rather than upper eyelid ptosis or blepharochalasis. These patients will require a brow lift alone, or in combination with a blepharoplasty, to correct their functional and aesthetic concerns.

Correction of brow ptosis can be achieved with either an open or endoscopic approach. The traditional open approach requires a transcoronal incision with resection of excess scalp or forehead. Unfortunately, this approach results in a long scar, potential scar alopecia, and anesthesia of the scalp and forehead. In addition, an open brow lift in male patients with a receding hairline requires resection of hair-bearing scalp, which is an undesirable outcome. To reduce these complications, the endoscopic brow lift was developed and has become the primary approach for repair of brow ptosis.⁵⁴ The endoscopic brow lift requires only three to five 1-cm incisions behind the hairline to gain access to the forehead and glabellar rhytids, producing less of an aesthetic deformity and limiting the amount of scarring. There is also evidence to suggest that the endoscopic approach produces a more lasting result than the traditional approach.⁵⁵ Lastly, it has been reported that anesthesia of the forehead and scalp is significantly reduced when an endoscopic approach is utilized for correction of brow ptosis, as compared to an open, transcoronal approach.

Endoscopic and open brow lifts may be performed under local or general anesthesia. Patients are marked preoperatively in the upright position. The desired brow position is at the level of the orbital rim in male patients and 1 cm above the orbital rim in female patients. The position of the brow in relation to the supraorbital rim changes from medial to lateral; the lateral brow should be more elevated than the medial brow. During an open brow lift, a coronal incision is made and the entire forehead is mobilized in a subgaleal or subperiosteal plane down to the orbital rim. The supraorbital and supratrochlear nerves are dissected free of surrounding tissues and preserved. The corrugator and procerus muscles are resected if prominent glabellar rhytids are present. Excessive resection of the corrugator muscles will result in widening of the eyebrows in the midline. The periosteum is released at the level of the supraorbital rim when a subperiosteal plane is utilized for mobilization of the forehead; the dissection is carried down to the level of the supraorbital rim when a subgaleal plane is used for forehead mobilization. The forehead is then elevated and redraped posteriorly, the redun-

dant scalp is resected, and the wound is closed. In an endoscopic brow lift, incisions are made within the hair-bearing scalp at the midpupillary line and over the temporal fossa. The entire forehead flap is elevated under endoscopic guidance, the procerus and corrugator muscles are resected as necessary, and the forehead is retracted posteriorly. The forehead is then secured into its new position. Various methods of forehead fixation have been described including absorbable and nonabsorbable plates, screws, multipronged anchors, and cortical tunnels.^{65,66}

Postoperatively, patients are instructed to avoid vigorous physical exercise for at least 6 weeks. Bruising and swelling are anticipated for the first 2 to 3 weeks following the procedure. The final result is not expected for at least 6 to 8 weeks following the procedure.

Rhytidectomy. The deleterious effects of aging, gravity, sun exposure, and smoking are particularly evident on the face. Ultraviolet radiation and tobacco use produce fine facial wrinkling and skin laxity as a result of the loss of skin elasticity. Aging and gravity result in gradual relaxation of the facial retaining ligaments producing midfacial ptosis, deepened nasolabial folds, "jowling" along the mandibular border, and redundancy of cervical skin.⁶⁷ Old family photographs and driver license photographs are constant reminders of a more youthful appearance with high cheekbones, a sharp mandibular border, and smooth skin. However, as the aging process marches on, patients may lose self-confidence and self-esteem in social, political, and business situations, encouraging them to seek facial rejuvenation surgery. If the patients are selected appropriately and the surgery is carefully planned and executed, the results will be gratifying for both patient and surgeon.⁶⁸

During the preoperative evaluation, the patient's expectations and motivations are carefully evaluated and addressed. Surgeons need to be cautious of patients whose concerns about their appearance are out of proportion to their physical deformity. Under these circumstances, a perfectly designed and performed operation may still have a dismal outcome in the eyes of the patient.

- 10 Patients who smoke are at a significantly increased risk for developing postoperative complications, including skin flap necrosis, infection, or wound dehiscence, and are consequently instructed to quit prior to undergoing elective aesthetic surgery. Many surgeons will refuse to perform a cervicofacial rhytidectomy in any patient who is actively smoking or utilizing any products containing nicotine. Urine cotinine levels can be determined to confirm whether a patient has been utilizing nicotine in any form. Older patients with coexisting medical illnesses are referred to a general practitioner for optimization of their medical condition preoperatively. If the patient is deemed a moderate or high risk for general anesthesia because of medical comorbidities, then the operation may be postponed until those medical conditions are optimized. Occasionally, if the risk of anesthesia is too high for a patient, then the operation may need to be cancelled.

Younger patients (40 to 50 years old) with good skin quality, mild midfacial ptosis, and early "jowling" may benefit from a minimally invasive facelift. This operation is typically combined with an endoscopic brow lift to provide upper and lower facial rejuvenation with minimal scarring. The operation is performed under local or general anesthesia. Bilateral temporal and superior buccal sulcus incisions are made. The temporal fossa dissection is carried down to the level of the superficial layer of the deep temporal fascia. Under endoscopic guidance, the superficial layer of the deep temporal fascia is then incised to expose the temporal fat pad. The dissection then proceeds caudally until the zygomatic arch is identified. A subperiosteal plane of dissection provides access to the midface while preserving the integrity of the frontal branch of the facial nerve. The subperiosteal plane of dissection is continued into the midface with care taken to avoid the infraorbital nerves. The masseter is mobilized from its lateral attachments.

The superior buccal sulcus incisions are made, and a midface subperiosteal dissection is performed under both direct visualization and endoscopic guidance. Once the dissection is completed, the entire midface is suspended in the desired position with sutures or specialized anchors spanning from the superficial layer of the deep temporal fascia to the midface periosteum. Symmetry of the suspension is then confirmed and the wounds are closed in layers. This technique will nicely correct mild midface ptosis, mild jowling, and early nasolabial fold prominence. However, this technique will not correct deformities from significant skin laxity. Under these circumstances, a traditional cervicofacial rhytidectomy will be required.^{65,69}

In patients who require resection of excess skin, a traditional rhytidectomy can be performed under local or general anesthesia. The skin incision is made over the temporal fossa 4 to 5 cm cephalad to the root of the helix and extended caudally toward the apex of the ear. The incision is then extended anterior to the ear, behind the tragus, around the base of the earlobe into the retroauricular sulcus, across the mastoid, and caudally along the anterior hairline of the neck. The skin flap is then elevated just superficial to the superficial musculoaponeurotic system (SMAS) and platysma. This plane of dissection maintains a thin layer of subcutaneous fat on the skin flap to preserve viability while avoiding injury to the facial nerve branches, greater auricular nerve, parotid gland, and jugular vein. The flaps are elevated medially to the nasolabial fold in the face and to the midline in the neck. Occasionally a platysmal diastasis may exist, which creates platysmal banding, an obtuse cervicomental angle, and a prominent neck. Under these circumstances, a platysmal plication may be performed through a 2- to 3-cm submental incision to correct the diastasis and improve the appearance of the neck. At this point, there are many variations in how the remainder of the cervicofacial rhytidectomy is performed with the goal of repositioning all of the tissues that have migrated into dependent positions creating facial aging changes. The surgeon may simply choose to not perform any additional dissection at this point and simply reposition the skin, resect the excess skin, and close the incisions. In other circumstances, the surgeon may choose to do one of the following: SMAS plication, standard SMAS dissection, extended SMAS dissection, or deep plane dissection. These operations are all designed to improve control of facial and cervical tightening while reducing the tension on the skin closure. Once the dissection of the facial tissues is completed and all planes are mobilized optimally, the SMAS and platysma are placed under tension and secured to create the desired facial appearance. The skin flaps are then redraped posteriorly, the patient is examined for symmetry, and a skin resection is performed. Hemostasis is obtained through judicious use of bipolar electrocautery. The wounds are closed in layers and a pressure dressing is applied. Drains are typically used in the face and neck.⁷⁰⁻⁷⁴

Postoperatively, the patient is evaluated in the recovery room for any evidence of a hematoma or facial nerve injury. It is crucial to identify a hematoma early to avoid overlying skin necrosis. Facial nerve injuries occur in only 2% to 3% of cases. On the first postoperative day, the pressure dressings and drains are removed and the patient is examined for evidence of a late hematoma, unrecognized facial nerve injury, or compromised skin flap. Patients should expect to have significant swelling and bruising for at least 2 weeks following the procedure. The final postoperative result is not realized until approximately 6 months following the procedure (Fig. 113.21).

Blepharoplasty. Eyelid surgery may be performed to correct functional or aesthetic deformities. Excessive skin and fat of the eyelids can give the patient an angry, aged, or tired look and may cause visual field obstruction. Older patients typically present with redundant skin and fine wrinkling, whereas younger patients commonly complain of persistent bags under their eyes or fine wrinkling (“crow’s feet”) at the lateral canthus. Treatment of each clinical entity requires a unique

approach based on the diagnosis and presentation.⁷⁵ All patients being evaluated for blepharoplasty require a complete ophthalmologic examination preoperatively to evaluate visual acuity, upper eyelid ptosis, exophthalmos, lower eyelid laxity, and symptoms of “dry” eye. Meticulous attention to detail is critical for the successful outcome of blepharoplasty surgery.⁶⁶ If there is lower lid laxity preoperatively, and a standard blepharoplasty is performed, the patient may develop a lower lid ectropion postoperatively. Symptoms of dry eye can also be significantly worsened by a blepharoplasty. As a result, it is critically important to perform a comprehensive evaluation of the health of the eye prior to performing any eyelid surgery.

Once a complete evaluation has been performed and a diagnosis has been made, an operative plan can be formulated to correct the concerns of the patient. The operation can be performed under local or general anesthesia. Older patients frequently require skin excisions and removal or repositioning of orbital fat. The blepharoplasty incisions are designed preoperatively with the patient in the upright position. Local anesthesia with epinephrine is then infiltrated for pain control and hemostasis. The upper eyelid blepharoplasty then begins with an elliptical excision of upper eyelid skin and orbicularis oculi muscle. The skin excision is designed based on the amount and location of the blepharochalasis. Very rarely will a patient require removal of fat from the upper eyelids. Excessive fat resections will produce a “hollowed-out” appearance. However, occasionally there may be a substantial amount of excess orbital fat in the upper eyelids and conservative fat resection may be helpful to achieve the desired postoperative outcome. If a fat resection is to be performed, small openings are made in the orbital septum to gain access to the two compartments of periorbital fat. A conservative fat resection is then performed to avoid a postoperative hollowed-out appearance. The skin is then redraped and the wounds are closed in a single layer. If an upper lid blepharoplasty is being performed in conjunction with a brow lift, the brow lift should be performed first, so that the amount of excess upper eyelid skin can be determined after the brow has been elevated.

The traditional lower eyelid blepharoplasty begins with a subciliary incision. A 4- to 5-mm rim of orbicularis oculi is then preserved along the lower eyelid margin. The dissection is then carried deep to the orbicularis oculi muscle until the orbital septum is identified. The orbital septum is then divided to gain access to the three compartments of periorbital fat in the lower lid. Fat may be resected in cases of prominent herniation, but overresection must be avoided. A trend in blepharoplasty surgery has emphasized periorbital fat repositioning rather than resection. Simply repositioning the herniated periorbital fat over the inferior orbital rim, rather than resecting fat, can dramatically improve the appearance of the lower eyelids.⁷⁶ The approach of repositioning the orbital septum medially has proven to be very helpful in eliminating tear trough deformities. Once the periorbital fat has been resected or repositioned, the skin/muscle flap is redraped superiorly and the redundant tissue is excised. The lower eyelid wounds are closed with interrupted sutures of 6-0 silk. Ancillary procedures may also be necessary to improve the position of the lower eyelid, including a medial canthoplasty, lateral canthoplasty, lateral canthopexy, or horizontal lid shortening. If a lower lid blepharoplasty is being performed in conjunction with a rhytidectomy, the rhytidectomy should be performed first, so that the amount of excess lower eyelid skin can be determined after the facial soft tissues have been elevated.

In younger patients, the tired appearance of the lower eyelids is commonly a result of excessive or herniated periorbital fat. A lower lid blepharoplasty through a transconjunctival approach allows removal or repositioning of the periorbital fat without an external scar. The conjunctiva is divided transversely 1 mm above the sulcus to gain access to the orbital septum. The septum is divided and the periorbital fat is removed or repositioned from all three compartments. Once again, the

FIGURE 113.21. Cervicofacial rhytidectomy with superficial musculoaponeurotic system resection, platysma plication, submental suction-assisted lipectomy, endoscopic browlift, and bilateral subciliary lower eyelid blepharoplasty. **A, B:** Preoperative appearance. **C, D:** Postoperative appearance. Note the dramatic improvement in the appearance of her neck, flattened nasolabial folds, improved definition of the mandibular border, and improved prominence of the malar regions.

emphasis has been to preserve periorbital fat and simply reposition the orbital septum into a more optimal location obviating the need for fat resections. The transconjunctival incision is then allowed to heal by secondary intention, allowing rejuvenation of the lower lids without an external incision.

Recently, a multiplanar approach for the rejuvenation of the lower eyelids has been employed to reduce the incidence of lower eyelid ectropion postoperatively. These approaches combine both subciliary incisions for removal of excess skin and a transconjunctival incision for repositioning or resection of the periorbital fat. Clinical case series from experienced plastic surgeons have demonstrated outstanding outcomes with this approach.

Postoperatively, patients are evaluated in the recovery room for corneal abrasions, changes in visual acuity, or

hematomas, which may require emergent intervention. No vigorous physical exercise is permitted during the early postoperative period. Artificial tears are used to maintain appropriate lubrication. Sutures are removed 5 to 7 days postoperatively. Patients are informed that they will be bruised and swollen for approximately 2 weeks and that it will be approximately 6 to 8 weeks before the final result will be seen.

Rhinoplasty. Rhinoplasty is an exacting operation to alter the external appearance and internal anatomy of the nose. The nose may be aesthetically unappealing or functionally impaired as a result of trauma, surgery, or a congenital deformity. Clearly, many familial and ethnic traits result in a multitude of nasal appearances. As a result, it is crucial that the patient and surgeon discuss the goals of the procedure and the likelihood of achieving

FIGURE 113.22. Open tip rhinoplasty with dorsal hump reduction including cartilage and bone, cephalic scroll resection of lower lateral cartilage, nasal septal cartilage spreader grafts, and nasal osteotomies. A, B: Preoperative appearance. C, D: Postoperative appearance. Note the nice reduction in the dorsal hump, supratip break, and improved dorsal aesthetic lines. The midvault collapse has been dramatically improved.

those goals. The patient must have realistic expectations and be prepared for the operation both physically and mentally.

To successfully achieve the goals of rhinoplasty, a complete nasal history is obtained with particular attention paid to nasal airway obstruction, allergies, trauma, and previous surgery. A photographic analysis is performed to evaluate facial and nasal dimensions. The photographs are examined with the patient, the operative plan is discussed, and the potential structural and functional outcomes are reviewed.⁷⁷

Rhinoplasty may be performed under local or general anesthesia. The patient is prepared for surgery by intranasal injections of vasoconstrictors containing lidocaine and epinephrine. Topical vasoconstrictors are applied to the nasal lining and septum. The operation can be performed in an “open” or “closed” fashion. The open technique requires a transcolumellar incision extended intranasally to allow exposure of the cartilage and bones of the nose. Direct visualization of the structure of the

nose allows greater precision in cartilaginous sculpting, grafting, and nasal bone repositioning. The paired lower lateral cartilages create the shape and provide the support for the nasal tip. Any deformity involving the nasal tip requires manipulations of this cartilage, including resections for a bulbous or overprojecting tip, suturing to reposition an asymmetric nasal tip, or cartilage grafting to increase tip projection. The paired upper lateral cartilages and nasal bones define the shape of the nasal dorsum and control nasal airflow. A prominent dorsal hump may require resections of both the upper lateral cartilages and nasal bones. Osteotomies of the nasal bones may be required to narrow nasal width by disconnecting the base of the nasal bones from the maxilla (Fig. 113.22). In contrast, “saddle nose” deformities may require cartilage or bone grafting to provide dorsal augmentation. Alloplastic materials have been described for use as dorsal grafts, tip grafts, or columellar struts to increase nasal projection. However, many surgeons

discourage use of such alloplastic grafts due to problems with infection, extrusion, and migration producing a suboptimal result acutely or chronically. Autogenous cartilage grafts from the nasal septum, ear, or rib may also be used to improve nasal appearance or airflow. These grafts can be harvested and sculpted to create the desired cosmetic appearance of the nasal dorsum and tip. “Spreader grafts” can also be placed between the nasal septum and the upper lateral cartilage to increase the size of the internal nasal valve area, improving nasal airflow.⁷⁸ The “closed” rhinoplasty technique allows access to the nasal cartilage and bones through intranasal incisions. Many experienced rhinoplastic surgeons prefer this less invasive approach. Unfortunately, it is difficult to perform many of the complicated cartilage grafting and suturing techniques with this limited exposure.

Postoperatively, patients are instructed to keep their head elevated and apply ice packs. An external splint is used to maintain the position of the nasal bones and cartilage for 10 to 14 days. Patients should expect nasal swelling, pain, and bruising for 2 to 3 weeks; if osteotomies are performed, the patient may also experience periorbital ecchymosis. A full year is required for complete resolution of nasal tip swelling, particularly following an open tip rhinoplasty. Approximately 10% of primary rhinoplasty patients will require an operative revision due to dissatisfaction with the cosmetic or functional outcome; the revision rhinoplasty should not be performed for at least 1 year following the original procedure to ensure that all postoperative swelling and tissue remodeling has stabilized.

Genioplasty. Genioplasties are common plastic surgical procedures to manipulate the position of the chin and thereby improve facial appearance. Based on the design of the mandibular symphysis osteotomy, the vertical height and anterior projection of the chin can be adjusted.⁷⁹ Patients with a “weak” chin may undergo an advancement genioplasty to enhance chin projection and improve the cervicomentale angle. Chin augmentation may also be accomplished with an alloplastic implant, eliminating the need for an osteotomy. Patients with a very prominent chin can undergo a reduction genioplasty where the vertical height and anterior projection can be reduced. The dental occlusion is not affected by these procedures, but the lip position and neck appearance may be altered.⁸⁰

A complete physical examination, photographic analysis, and radiographic evaluation are performed to evaluate facial harmony and determine the extent of the advancement or reduction. Dental occlusion is carefully examined to ensure that orthognathic surgery is not required to correct chin position.

Operations are typically performed under general anesthesia, but can also be performed under local anesthesia if desired. Local anesthesia containing epinephrine is injected intraorally for hemostasis and postoperative pain control. Access to the mandibular symphysis is achieved through an inferior buccal sulcus incision. The osteotomy is measured and marked based on the preoperative photographs and lateral radiographs; the mental foramen is avoided. The bony segment is mobilized and secured in its new position with plates and screws. If an alloplastic chin augmentation is to be performed, incisions can be performed in the submental region or intraorally for placement of the implant. Postoperatively, swelling and pain persist for approximately 4 to 6 weeks. During this time, the patient should perform meticulous oral hygiene and avoid foods that may traumatize the inferior buccal sulcus incision.

Cosmetic Procedures of the Trunk and Extremities (Body Sculpting)

Abdominoplasty. Abdominoplasties encompass a wide array of surgical procedures used to correct abdominal deformities

resulting from excess abdominal skin, fatty tissue, and abdominal wall laxity. Abnormalities in any of these tissue planes may produce an aesthetically unappealing abdomen. Surgical procedures are designed to correct the underlying pathology and include dermatolipectomy, liposuction, and abdominal wall plication. These procedures are often combined and tailored to fit the surgical needs and desires of the patient. It is critical to define the physical anomaly responsible for the abdominal deformity so that the appropriate operative procedure or combination of procedures can be performed.^{81,82}

A standard abdominoplasty combines a dermatolipectomy, liposuction, and abdominal wall plication to correct deformity in each of the three previously mentioned abdominal wall layers. The operation is performed under general anesthesia through a bikini-line incision extending from the cephalad margin of the pubic escutcheon to the iliac crests bilaterally. The skin incisions are made and the abdominal flap is elevated off the underlying abdominal wall fascia. A circumferential incision is made around the umbilicus to allow complete elevation of the abdominal flap up to the costal margin. The patient is then placed in a flexed position, the abdominal flap is redraped caudally, and the redundant skin is resected. If any abdominal wall laxity is identified along with the skin redundancy, then a vertical, midline abdominal wall plication is also performed. Occasionally, suction-assisted lipectomy (SAL) is performed at the time of abdominoplasty to help recontour the abdomen and flanks. However, aggressive SAL of the abdominal flap may critically compromise flap vascularity and contribute to flap necrosis. Occasionally, it is helpful to perform SAL along the lateral and posterior iliac crests bilaterally to reduce the prominence that may have developed following the anterior dermatolipectomy and caudal repositioning of the skin flap. A small incision is then made in the midline of the abdomen at the level of the iliac crests for delivery of the umbilicus into its new position. Closed-suction drains are placed prior to wound closure (Fig. 113.23).

A “mini-abdominoplasty” is used to treat mild abdominal skin redundancy and abdominal wall laxity. The same approach is used as previously described for a standard abdominoplasty except the skin incision is limited to the central portion of the abdomen. A limited skin resection can be performed through this approach along with an abdominal wall plication. SAL can be used in combination with this procedure if necessary.

Endoscopic abdominoplasty can be used to treat abdominal wall laxity (i.e., postpartum rectus diastasis) and localized collections of fatty tissue. Patients who are candidates for this operation must have good skin quality and only mild to moderate lipodystrophy. The endoscopic abdominoplasty is performed through two incisions, a 3- to 5-cm transverse incision within the pubic hair and a circumferential incision around the umbilicus. These incisions function as the two access ports through which the endoscopic instruments are passed. The entire abdominal wall is then elevated off of the abdominal wall fascia under endoscopic visualization with electrocautery. The midline of the abdominal wall is plicated from pubis to xiphoid. The abdominal wall is then recontoured with SAL, which is performed through the two access ports.⁶³

Liposuction. Liposuction is a surgical procedure designed to resect collections of fat from isolated anatomic regions. Liposuction is not a form of weight loss and is not indicated in obese patients. Liposuction is ideally suited to patients who are within 20% to 30% of their ideal body weight and have localized collections of fat that are refractory to dietary modifications and exercise. A complete evaluation of skin elasticity is very important in patients considering liposuction because once fat is surgically removed, the skin must be able to contract down to the contour of the remaining subcutaneous tissue. If the skin quality is poor, then wrinkling, dimpling, or skin ptosis may severely compromise the aesthetic result.^{81–83}

FIGURE 113.23. Mastopexy, abdominoplasty, and rectus abdominis plication. A, B: Preoperative appearance of breasts. C–E: Preoperative appearance of abdomen. (*continued*)

Two forms of liposuction are currently used: SAL and ultrasonic-assisted liposuction (UAL). SAL is used in all areas of the body but may not be as effective as UAL in more fibrous anatomic regions such as the flank, upper abdomen, or male breast. Treatment of lipodystrophy in these regions is more effective with UAL alone or UAL in combination with SAL.^{84,85,87} A number of technologic advances have led to new techniques for performance of liposuction or liposculpting (i.e., Lipodissolve, Endermologie, Smart-lipo). However, none of these newer devices or techniques has proven to be effica-

cious in rigorous clinical trials, nor have they been shown to be as effective as standard SAL or UAL.

As with all aesthetic procedures, careful patient selection is of paramount importance. All patients must undergo a complete evaluation preoperatively to ensure that their goals can be achieved by performance of liposuction. Preoperative photographic documentation is performed on all patients. Markings are then made with the patient in the upright position. Access ports (6 to 8 mm), through which the SAL or UAL is performed, are marked in concealable areas. Patients can

FIGURE 113.23. (Continued) F–H: Postoperative appearance. Note the dramatic improvement in the appearance of the breasts and abdomen. The abdomen is flat with a narrowed waistline.

undergo these procedures under local or general anesthesia. Tumescence fluid (1,000 mL of lactated Ringer, 50 mL of 1% lidocaine, and 1 mg of epinephrine) is then infiltrated for pain control and hemostasis.

SAL is performed with metal cannulas connected to an aspirating device that generates a negative pressure of 1 atmosphere. Various cannula configurations are used to perform the resection. Fatty tissue is aspirated into the holes of the cannula and then resected by movement of the cannula

tip. The operation is performed through multiple access ports, starting with large (6- to 8-mm-diameter) cannulas and progressing to smaller (3- to 4-mm-diameter) cannulas with fewer holes to allow more precise body contouring. Overlapping patterns of resection are used to avoid contour irregularities.

UAL is a surgical technique that allows body contouring through the liquefaction and aspiration of fatty tissue. When employed alone or in combination with traditional SAL, UAL

is effective for treating lipodystrophy in fibrous anatomic regions such as the flank, upper abdomen, and male breast. The UAL probe tip produces sound waves at an ultrasonic frequency of 20 to 30 kHz. The effect of these sound waves is to cavitate and liquefy to low-density lipocytes. Low-power suction is then employed to remove the resultant fluid. If UAL is used inappropriately, patients may experience severe complications, including full-thickness skin loss from thermal injury.⁸⁶

All patients are placed in a compressive garment 24 hours per day for 6 weeks postoperatively. Early postoperative compression reduces the chances of hematoma formation. Prolonged compression reduces swelling and the potential for skin wrinkling. All patients experience some degree of ecchymosis, swelling, and decreased sensibility. The end result will not be realized for approximately 2 to 3 months following the procedure.

PEDIATRIC PLASTIC SURGERY

The specialized area of pediatric plastic surgery focuses on the reconstruction of abnormalities in children with congenital malformations and acquired deformities. Utilizing a sound knowledge of embryology as well as the changes inherent during growth and development, pediatric plastic surgeons employ a combination of innovation and technical expertise to restore both form and function to their patients. Although the manifestations of congenital malformations may be diverse, the approach to reconstruction is always based on solid fundamental surgical principles. Similarly, the management of traumatic or other acquired maladies in the pediatric population is founded on essential surgical tenets influenced by the special considerations of maturation and growth. This section concentrates on the most salient aspects of pediatric plastic surgery to give the clinician an accurate grasp of the subspecialty.

Cleft Lip and Palate

Perhaps the area of expertise that best exemplifies the specialty of pediatric plastic surgery is the management of children with cleft lip and palate deformity. The cleft lip and palate pose a variety of structural and functional deficits that must be addressed with respect to growth and development as well as psychosocial concerns of the individual patient and family. The care of these children requires exacting surgical technique in combination with the efforts of a team of allied health professionals to effect a comprehensive level of rehabilitation.

The overall incidence of cleft lip and palate deformity is approximately 1 in 750 children. This incidence is significantly higher in the Asian population, 1 in 300, and significantly lower in the black population, 1 in 2,000.⁸⁷⁻⁹⁰ The distribution of cleft types is approximately 46% combined cleft lip and palate, 21% isolated cleft lip, and 33% isolated cleft palate.⁹⁰

FIGURE 113.24. Left unilateral complete cleft lip. (Adapted from Jurkiewicz MJ, Krizek TJ, Mathes SJ, eds. *Plastic Surgery: Principles and Practice*, Vol 1. St. Louis, MO: Mosby; 1990:64.)

Almost 30% of children with cleft lip and palate deformity have associated birth defects that vary in scope and extent and therefore require vigilance in the physical examination.⁹¹ The chance of having a second child with cleft lip and palate to unaffected parents is approximately 4%, as is the chance of one affected parent producing an offspring with a cleft.^{91,92} Genetic counseling is usually helpful in both educating the parents and screening for other associated congenital anomalies.

11 A cleft lip deformity can be bilateral or unilateral and is considered *complete* if it extends into the nose and *incomplete* if it does not (Fig. 113.24). The cleft lip can extend into the gum partially or completely through the alveolus, creating a bony defect. The cleft lip deformity affects the nose as well as the lip, and therefore both of these structures must be addressed in the reconstruction of the deformity. Although the timing of cleft lip repair is controversial, the repair of the cleft lip is most often addressed in about the third month of life, after the child shows sufficient weight gain. This timing permits a potentially safer anesthetic administration.

There are multitudes of cleft lip repairs, but the goals of the repairs remain the same: an anatomic reconstruction with minimal scarring and normal function. In general, the skin around the cleft is cut into flaps that are brought together in a way that will give adequate length to the lip and restore the continuity of the orbicularis musculature (Fig. 113.25). Symmetry is the mainstay of reconstructive procedures to the cleft lip, allowing the normal side of a unilateral cleft to serve as a template for restoration and ensuring equal balance and proportion in a bilateral cleft repair.

The cleft palate can affect the soft palate alone or include the hard palate. A unilateral cleft of the hard palate exposes only one side of the vomer, whereas a bilateral cleft of the hard

FIGURE 113.25. Millard rotation—advancement lip repair. (Adapted from Jurkiewicz MJ, Krizek TJ, Mathes SJ, et al. *Plastic Surgery: Principles and Practice*, Vol 1. St. Louis, MO: Mosby; 1990:71.)

FIGURE 113.26. Cleft palate. (Adapted from Jurkiewicz MJ, Krizek TJ, Mathes SJ, et al. *Plastic Surgery: Principles and Practice*, Vol 1. St. Louis, MO: Mosby; 1990:84.)

palate exposes both sides of the vomer (Fig. 113.26). The cleft of the hard palate can be continuous with an alveolar defect from a cleft lip, resulting in an opening that runs from the most anterior portion of the lip through to the back of the uvula. In some cases, a cleft palate may have no mucosal separation at all and display only a separation or clefting of the underlying musculature. This special situation is referred to as a submucous cleft palate and may also have functional consequences for the patient.

Functionally, the hard palate acts as a structural barrier between the oropharynx and the nose. The soft palate moves superiorly and articulates with the posterior and lateral pharyngeal walls to effect a seal between the oropharynx and the nasopharynx during speech and swallowing. The coordinated activity of the soft palate prevents regurgitation of solids and liquids into the nose while eating and prevents hypernasal speech while producing strictly oral sounds.

As with cleft lip, there are a multitude of cleft palate repairs but the goals of the repairs remain the same: an anatomic reconstruction with minimal scarring and normal function. Reconstructive procedures are based on reconstituting the oral and nasal lining of the palate and reapproximating and realigning the palatal musculature. A purely soft palatal cleft may require only the separation of the layers of the palate, reapproximation of the muscles, and simple closure. The wider clefts and many of the hard palatal clefts, however, require relaxing incisions and release of the mucosa from the underlying bone. The lateral mucosa from both sides is transposed over the midline cleft and sewn closed (Fig. 113.27). Flaps derived from the vomer may be required to achieve closure without tension, a chief precept for any repair of the palate. The dissection of mucosal tissue off the bone is thought to contribute to the severe growth restriction of the midface and bony palate exhibited by many of the children with this deformity.^{93,94} A delay in the procedure is thought to enhance the growth of the midface and palate, whereas early intervention is thought to improve speech. For this reason, the timing of the repair of the cleft palate is controversial; however, the cleft palate repair is most often addressed by the age of 1 year.

Speech therapy is almost always required for children with a cleft palate and is instituted as soon as the child develops the necessary language skills. “Early on” programs have arisen for preschoolers, and speech programs are often available through local school systems. Unfortunately, the palate repair alone is successful in normalizing speech in only about 80% of patients.⁹⁵ The remainder of patients will require a supplemental operation to decrease residual hypernasality and improve speech. The operations directed at salvaging speech are performed early enough to have the most beneficial effect on speech development while giving adequate time to ensure that the patient has been given ample opportunity for speech therapy to maximize the potential of the palate repair. The decision to operate is based on a perceptual analysis of speech and is aided by visualization of palatal function with nasendoscopy and objective measures of function using nasometry techniques. Techniques vary, but the operative procedures are based on placement of either dynamic or static tissue near the velopharyngeal port to better regulate and impede the abnormal flow of air into the nasopharynx.

Orthodontics is a key portion of the comprehensive restoration of the cleft patient and requires close interaction

FIGURE 113.27. A: Von Langenbeck palatoplasty. B: Nasal mucosa and levator muscles approximated. C: Layered closure of oral mucosa and lateral relaxing incisions. (Adapted from Jurkiewicz MJ, Krizek TJ, Mathes SJ, et al. *Plastic Surgery: Principles and Practice*, Vol 1. St. Louis, MO: Mosby; 1990:91.)

between the pediatric plastic surgeon and the orthodontist. One of the early interactions involves the repair of any residual clefting of the alveolus. Bone grafting is required for reconstruction of the alveolar cleft to restore the continuity of the upper maxillary dental arch, allow the normal emergence of the canine tooth, close the persistent oral nasal fistula, and provide structural support for the recessed nasal alar base. The orthodontist will monitor tooth eruption and may institute early-phase therapy to align the teeth in preparation for bone grafting. The timing of alveolar bone grafting is also controversial but is mandatory for normal tooth emergence. Bone grafting is often performed at about 7 to 8 years of age and entails the surgical isolation and excision of the oral nasal fistula, the reconstruction of the adjacent nasal floor and palatal roof, the placement of bone graft in the alveolar defect, and coverage anteriorly with gingival flaps. The bone grafts are most often cancellous in composition and can be taken from the iliac crest or the cranial diploe.

Many patients respond favorably to the skilled implementation of a long-term orthodontic plan, but some patients display bony hypoplasia as mentioned earlier and require orthognathic surgery of the maxilla, and possibly the mandible, to assist in establishing normal occlusion. Operations to restore a normal occlusion should await the cessation of growth so that the surgical registration of occlusion will be permanent and not require additional procedures. The most common operation to address midfacial hypoplasia and restore occlusion in the cleft patient is the Le Fort I osteotomy. The orthodontist helps the pediatric plastic surgeon to determine the best postoperative occlusion for the patient based on the orthodontic plan, and an oral surgical splint is fashioned to allow easy registration intraoperatively. The patient undergoes a horizontal osteotomy above the level of the tooth roots and across the nasomaxillary and zygomaticomaxillary buttresses below the level of the zygomatic body (Fig. 113.28). The bones of the midface are separated from the cranial base by performing a pterygomaxillary disjunction, and the floating maxilla is then repositioned into the planned occlusion by registering the teeth in the splint. The bones of the maxilla are then fixed using plates and screws. In severe malocclusion cases, the mandible may also need to be cut and reregistered into a position that results in an anatomic orthognathic bite.

FIGURE 113.28. Le Fort I osteotomy in an advanced position. One side has been plated into position. (Adapted from Jurkiewicz MJ, Krizek TJ, Mathes SJ, et al. *Plastic Surgery: Principles and Practice*, Vol 1. St. Louis, MO: Mosby; 1990.)

The last operation to be performed on the patient with a cleft lip and nasal deformity is often the formal rhinoplasty. There is almost always a septal deviation that must be addressed in these patients and is an important part of the procedure. Each rhinoplasty is necessarily individualized, but the procedure usually entails repositioning and trimming of the nasal tip cartilages, added support to the nasal tip and slumping lower lateral cartilages to achieve projection, straightening of the septum, and finally infracturing of the widened nasal bones.

Although the care of the cleft patient requires interaction with the pediatric plastic surgeon and the cleft team throughout the patient's childhood, it should remain a small and unobtrusive part of life. The number of operations is kept to the minimum needed to attain an adequate reconstruction as deemed necessary by both the patient and the doctor. Revisional surgery is usually an important part of cleft care but should be guided by the principle that the intervention is done *for* the child and not *to* the child, with an attempt to empower the patient as often as possible.

Craniosynostosis

- 12** Craniosynostosis is defined as the premature fusion of one or more of the cranial sutures. The child afflicted with craniosynostosis displays abnormalities in the size and shape of the cranial vault. Virchow's law proposes that the growth of the skull will be restricted in the direction perpendicular to a synostosed suture while compensatory growth occurs in a parallel direction.⁹⁶ The ensuing skull shape of the patient provides the nomenclature of the deformity and is primarily empiric in nature (Fig. 113.29). Synostosis of the metopic suture most often results in a triangular forehead and is referred to as *trigonocephaly*. Unilateral coronal suture involvement often results in a recessed or slanted supraorbital bar and forehead and is referred to as *plagiocephaly*, whereas bilateral coronal synostosis often results in a shortened and flattened forehead referred to as *brachycephaly*. The sagittal suture is the most commonly fused suture and results in a boat- or keel-shaped head referred to as *scaphocephaly*.

The abnormal shape of a craniosynostotic skull can often be severe and progressively worsen with time as the expanding brain reinforces and emphasizes the deformity. In addition, a small percentage of patients with a single-suture synostosis, and a much larger percentage of children with multiple-suture synostoses, are at risk for the development of increased intracranial pressure.^{97,98} The care of these patients, therefore, requires close interaction between a pediatric neurosurgeon and a pediatric craniofacial plastic surgeon. A thorough clinical evaluation is mandatory and an ophthalmologic evaluation to check for papilledema can be beneficial. A CT scan is also useful in these patients to confirm the diagnosis and assess the ventricular system as well as the neuroanatomy for possible associated developmental anomalies of the brain.

Once the functional aspects of craniosynostosis are evaluated and addressed, the operative strategy is then aimed at restoring normal morphology. The operation is tailored to the individual diagnosis and malformation, but the underlying surgical principles remain the same. A sinusoidal coronal incision in the scalp is used to afford access to the cranium and to hide the scar. The pediatric neurosurgeon performs a craniotomy to provide access to the cranial vault. In the case of plagiocephaly and trigonocephaly, the craniofacial pediatric plastic surgeon removes the frontal bar by performing a bilateral osteotomy at the lateral orbital rim and along the orbital roof, meeting in the midline with a cut across the region just above the glabella. The frontal bar is removed, bent and reshaped, and replaced in an advanced position as a bandeau or with interposition bone grafts placed to support the reconstruction. The bones of the forehead are similarly cut, bent and reshaped, and placed into a normal anatomic position. The bones are fixed with small

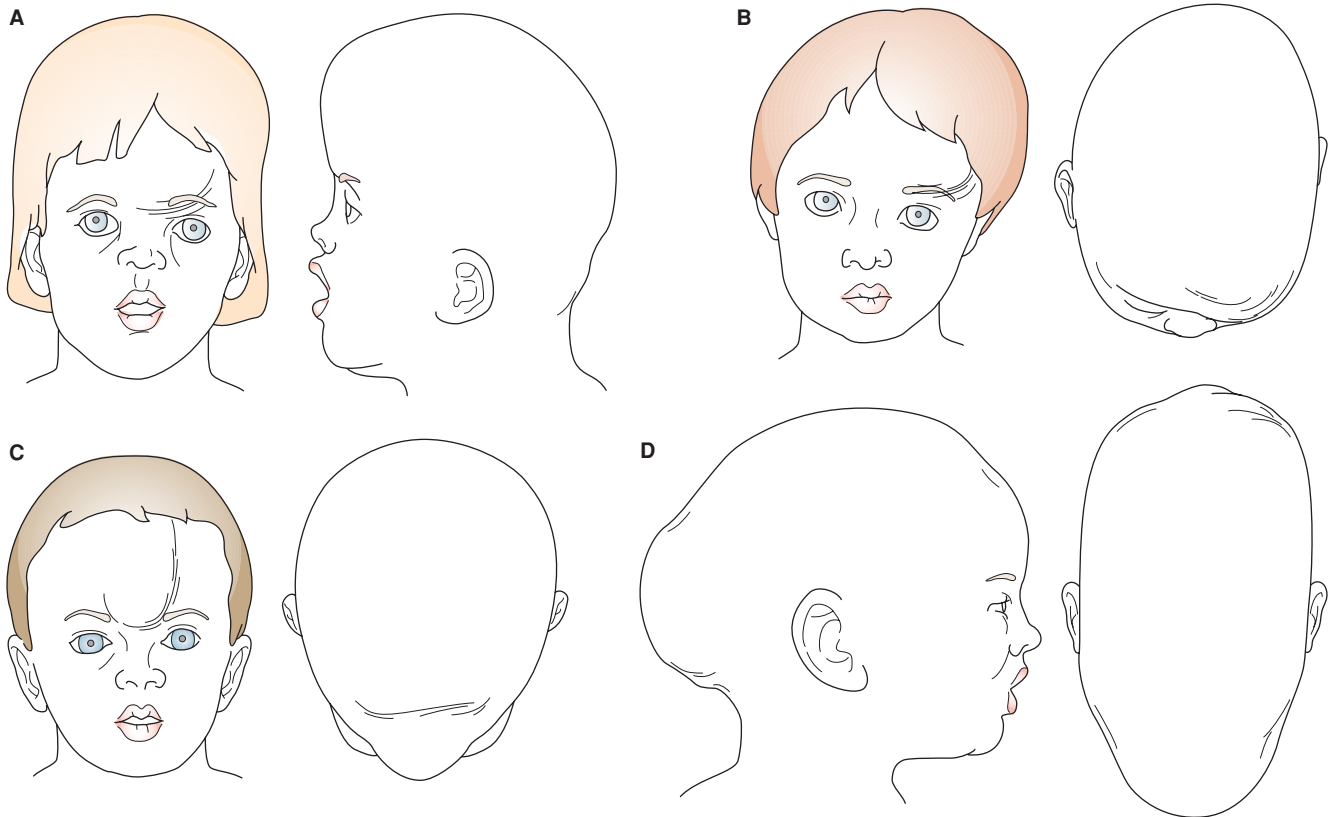

FIGURE 113.29. A: Turribrachycephaly (short, flat head). B: Plagiocephaly (slanted head). C: Trigonocephaly (triangular head). D: Scaphocephaly (keel-shaped head). (Adapted from Jurkiewicz MJ, Krizek TJ, Mathes SJ, et al. *Plastic Surgery: Principles and Practice*, Vol 1. St. Louis, MO: Mosby; 1990:119.)

metal or resorbable plates and screws (Fig. 113.30). A gap is left in the area of the coronal suture to allow growth and expansion of the brain. During infancy the dura is osteogenic and fills the gap in slowly with newly formed bone. In the case of a sagittal synostosis, the frontal bar often need not be removed; the operation entails the creation of barrel stave osteotomies in the parietal skull and outfracturing of the bone. The forehead is then back-fractured and gently posteriorly repositioned, the occipital bone is then fractured and gently anteriorly repositioned, and the bones are then fixed into position with the aid of bone grafts. During gentle repositioning the brain takes on a rounder shape filling out behind the parietal bone outfracture. This arrangement encourages subsequent growth to fill out the parietal region and secure a more anatomic shape. Other approaches to sagittal craniosynostosis include “strip craniectomy” whereby the synostosed suture and a few-

centimeter margin of bone on either side are removed as a strip. Due to unpredictability of the repair, postoperative helmeting protocols are often added to coax subsequent growth and remodeling of the skull into a more normal shape.

In the case of syndromic craniosynostosis patients, such as those with Apert, Crouzon, or Pfeiffer syndrome, similar reconstructions may be required for the cranial vault. Additional operations are often needed, however, to address deformities of the orbits and midface. In contrast to the midfacial hypoplasia exhibited by the cleft patient, the patient with syndromic craniosynostosis has a much more severe and extensive deformity and therefore requires more involved operations. Le Fort III and Monoblock operative procedures that move the entire upper and midfacial region forward can be used to vastly improve the appearance of the patient while establishing a more normal functional anatomy (Fig. 113.31). These operations

FIGURE 113.30. A: Plagiocephalic head viewed from above. B: The surgeon removes the bone of the forehead and advances the forehead to allow the brain to grow and the skull to resume a normal shape. FIGURE 113.31. Monoblock frontofacial advancement. (Adapted from Jurkiewicz MJ, Krizek TJ, Mathes SJ, et al. *Plastic Surgery: Principles and Practice*, Vol 1. St. Louis, MO: Mosby; 1990:119.)

address the bulging eyes, malar hypoplasia, and recessed and diminutive nasopharyngeal airway of these patients, restoring normal eye position and opening up the breathing passages to relieve obstructions of the airway and symptoms of sleep apnea.⁹⁹

Hemangiomas and Vascular Malformation. The pediatric plastic surgeon is often the primary caregiver for children afflicted with cutaneous hemangiomas and vascular malformations. These lesions may present at birth or in the neonatal period and require careful diagnosis and management. Hemangiomas are benign tumors that most often arise just after birth and undergo a spontaneous rapid growth phase followed by a slow involutional stage.^{100,101} In general, management of hemangiomas is nonoperative; however, ulceration or interference with function may require intervention. The use of systemic or local steroids may induce an involutional regression, but operative intercession may be necessary. Surgical strategies should strive to conserve tissue and function, avoiding the creation of significant deformities that would necessitate extensive and delayed reconstruction.

Vascular malformations are usually made up of veins, lymphatic vessels, capillaries, or a combination of each. The malformations are usually present at birth and grow in proportion to the patient. There is usually neither a growth phase, as in a hemangioma, nor an involutional stage. Small capillary hemangiomas such as port-wine stains are well treated with pulse dye laser therapy, and larger, more involved lesions may be better treated with a combination of surgical intervention and laser treatment. Lymphangiomas are difficult to treat because they are diffuse and often adjacent to vital structures. Staged partial excisions can be performed if there are functional indications for intervention.

Nevi

Congenital nevi are perhaps the most common benign tumor seen by the pediatric plastic surgeon. The small- to moderate-size nevi are usually of little consequence but need to be monitored closely for any significant changes in size, shape, color, bleeding, or ulceration. The potential for malignant degeneration into a melanoma for small- to moderate-size congenital nevi is controversial. The figures reported in several studies range so widely as to make a reasonable estimation difficult.⁸⁹ Serial examination and even photographs can be helpful to document changes over time, and the “gold standard” for any doubtful skin lesion is still excisional biopsy.

Giant hairy congenital nevi are larger and rarer, but they can be quite devastating to a child and the family. These lesions can affect the entire body or vast areas, including vital structures such as the eyelids, anus, and external sexual

organs. A reasoned and conservative approach to such difficult cases is mandatory. It is often helpful to enlist the aid of a dermatologist and the patient’s pediatrician to assist in monitoring these lesions. Again, photographic documentation is helpful in serially assessing these lesions. Areas that show significant change warrant incisional biopsy and pathologic evaluation. The aesthetic consequences of these lesions often can be severe, and the parents often want them to be excised. The surgical approaches to benign giant hairy congenital nevi are varied and range from excision and grafting to serial excision as well as the use of tissue expansion.

The use of extensive skin grafting as a reconstructive option for the reconstruction of giant hairy congenital nevi is usually reserved for malignant or dysplastic lesions. Skin grafts are not particularly durable long term, and they are often aesthetically displeasing and require subsequent resection and reconstruction. Serial excision can be useful in limited giant hairy congenital nevi, especially in locations near tissues that stretch well. The tissues adjacent to the lesion are undermined and advanced over the nevus to determine the amount that can be resected, and then a portion of the nevus is excised and the tissues are then reapproximated and allowed to heal. After 4 to 6 months the same procedure is performed until the nevus is fully excised. Tissue expansion requires the placement of a tissue expander adjacent to the lesion with slow instillation of saline into the expander over time, allowing stretching and recruitment of new tissue near the nevus to assist in excision and closure. If the expansion is not adequate in size, it can be removed after full expansion and replaced with a larger expander to fully expand the tissue. The quality and thickness of the skin, the possibility of exposure and infection, and the cooperation of the young patient at times limit the usefulness of this technique.

Prominent Ears

Prominent ears are a deformity that is mainly in the domain of the pediatric plastic surgeon. Children with prominent ears are prone to ridicule by classmates in school, teasing by siblings, and thoughtless comments by insensitive adults. The deformity does not usually present with an enlarged ear but rather with a lack of an antihelical fold, either with or without conchal hypertrophy. The remedy is aimed specifically at the deformity. An incision is made on the posterior portion of the ear exposing the cartilage, and sutures are placed in a mattress fashion to reconstruct an antihelical fold. The stiff conchal cartilage can be shaved, and the concha is then secured to the mastoid fascia using permanent suture. A strict postoperative head-banding protocol may be used to avoid trauma to the ear and allow undisturbed healing. Successful otoplasty is one of the most rewarding procedures performed by a pediatric

plastic surgeon because the child usually wants the surgery and is rewarded with immense satisfaction.

Myelomeningocele

The interaction between the pediatric neurosurgeon and the pediatric plastic surgeon often extends beyond the realm of craniofacial surgery. A prime example of the symbiotic interaction between the two specialties is in the repair and reconstruction of the myelomeningocele, which is a form of spina bifida. The neurosurgeon is often presented with an exposed dural sac and a wide-open skin defect. The neurosurgeon may be faced with a tenuous dural closure and may need to resort to the use of a homograft to achieve an adequate dural repair. The pediatric plastic surgeon can assist by closing the defect over the dural reconstruction with stable, reliable coverage using well-vascularized tissue, protecting the neurosurgeon's repair. The soft tissue coverage may require local paraspinal muscle flaps or various fasciocutaneous flaps, but the goal of a durable reconstruction with a normal contour is paramount so as to avoid persistent long-term complications both at the level of the skin and at the level of the dural repair (Fig. 113.32).

SUMMARY

Although there are a multitude of additional procedures and topics in the specialized domain of the pediatric plastic surgeon, such as pediatric facial trauma, facial reanimation surgery, and various deformities resulting from congenital hypoplasia and hyperplasia, this chapter has focused on some of the major and more common areas of patient management. In fact, the pediatric plastic surgeon is often a chief collaborator with many of the pediatric surgical services when presented with a case of challenging wound care or any case that poses a reconstructive dilemma. Continuing innovation and technical advances combined with an appreciation for sound fundamental surgical principles allow the specialty to continue meeting that challenge.
